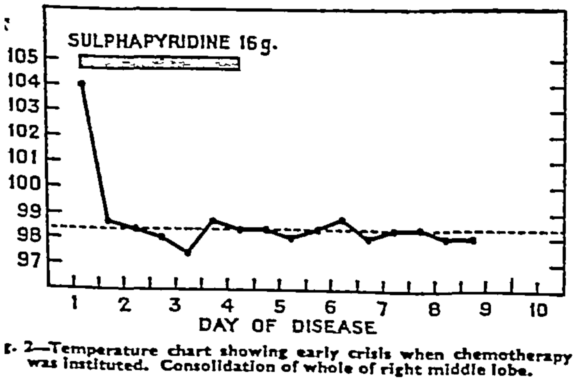
er 14 days	65	14	2

DISCUSSION

dence and Fatality

ice (1944) states that among negroes in America on the Rand the incidence and case-mortality of onia are high; Conybeare (1943) that the negro s are specially susceptible to pneumonia; and r (1942) that in the U.S.A. the disease is more fatal egroes than to whites. According to Gelfand (1944), umonia, next to malaria, is the commonest acute ss among South African natives, accounting for y deaths. He comments on such predisposing ors as bilharziasis, hookworm, and chronic malaria, believes that nutritional disorders and poor living ditions may reduce resistance. Civilian medical cers in Sierra Leone do not describe a benign e of pneumonia in negroes, but among civilians a rule only the more serious cases find their way hospital.

actors probably contributing to the benign clinical ture in the present series were that all patients were nitted to hospital as soon as possible; they showed sign of malnutrition; very few were suffering from onic infestation; their living conditions were good; they had not undergone the hardships of active vice. Early hospital treatment under almost ropean conditions was undoubtedly very important. ough they seemed just as susceptible to attacks of disease as their civilian brethren their resistance to was apparently much higher.



t. 2—Temperature chart showing early crisis when chemotherapy was instituted. Consolidation of whole of right middle lobe.

Gelfand and Lewis (1942) and others have described the frequency with which jaundice is met with in the coloured races as a complication of pneumonia. It was present in only 5 cases in this series, including the 1 death where an acute hæmolysis was associated with sickling of the red cells. In 1 other case the blood showed some evidence of hæmolysis, but the remaining 3 were cases of toxic hepatitis. These 3 patients recovered rapidly, and the jaundice seemed to have no bearing on the severity of the illness. Turner et al. (1943) in the U.S.A. have suggested that the high incidence of icterus observed in negro patients with lobar pneumonia was due primarily to nutritional deficiencies, which rendered the liver more vulnerable to the effects of pneumococcal infection.

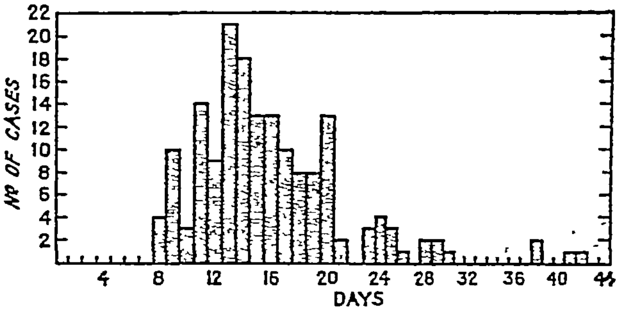


Fig. 3—Length of stay in hospital (average about 14 days).

The findings in general are similar to those of MacNaught and Murray-Lyon (1943) and suggest that pneumonia in the West African soldier in his own country is more benign than that encountered among African civilians or in negroes living in other parts of the world.

White-cell Counts

Though the great majority of cases of classical type showed a leucocytosis, 18 (17%) of this group had white-cell counts below 10,000, and of these 14 were regarded as very mild. This may be due to the type of infecting organism, 6 of these cases being due to a *Strep. viridans*, and 4 to a pneumococcus; or to the fact that only a portion of a lobe was involved in the pneumonic process, as in 84% of all cases without a leucocytosis only part of a lobe was involved.

A high white-cell count was mainly associated with an acute chest picture, sudden onset, high temperature, and early consolidation in which the whole of a lobe was involved. 15 out of 17 cases classified as atypical on clinical grounds had white-cell counts below 10,000, a finding which may now be regarded as orthodox.

Bacteriology

Perhaps the most interesting feature of this investigation was the isolation of pure cultures of *Strep. viridans* as the causal organism in 14 cases of classical type, 4 of abortive type, and 2 where the physical signs were those of simple bronchiolitis. A pure culture of pneumococci was obtained in only 28 cases. The predominant clinical picture produced by a *Strep. viridans* infection was that of a mild classical pneumonia, whereas that due to pneumococcal infection was on the whole more severe. Streptococcal cases resolved less often by crisis than pneumococcal cases, whether they received chemotherapy or not.

It has been established by Morgenroth et al. (1925) that there are close affinities between the pneumococci and the streptococci of the *viridans* group. In this investigation bile solubility was adopted as the final criterion of differentiation.

Atypical and Abortive Types

In some streptococcal cases the clinical picture was rather similar to that of atypical pneumonia as described by Turner (1945) in his Italian series, and the normal white-cell count in 6 of the present series seemed to support a theory that the *Strep. viridans* might be a causal organism of some varieties of atypical pneumonia. Much depends on the definition of "atypical," and though some of these cases were so benign as to be "not typical" of the classical pneumonia of older writers they did not fall into the clinical atypical group as defined here. In no case so defined was bacterial infection demonstrated, which supports the view that they are caused by a virus.

Almost 10% (16) of all cases have been classified as abortive. In 3 there were never any abnormal physical signs in the chest, and the radiological appearances were those of faint central opacities; yet the temperatures and white-cell counts were high.

One patient was of special interest. He was admitted with a temperature of 103°F of acute onset. This rose to 105°F the same evening, the pulse-rate was 120, and the respiration-rate was 30 per min. He presented an acute chest picture, with difficult respiration and an expiratory grunt. He had pain in the chest, expanding alæ nasi, and an irritating cough, which rapidly became productive. The sputum became rusty and mucopurulent, streaked with flecks of bright blood. On culture a heavy pure growth of pneumococci was obtained. The white-cell count was 16,500 per c.mm., mainly polymorphs. No malarial parasites were seen in repeated blood films. Radiography of the chest was normal both on admission and on two subsequent occasions. The urinary chlorides were not diminished at any time. No specific therapy was given, and the temperature fell to 99·4°F on the morning of the second day, was normal in the evening, and remained so. There were no abnormal physical signs in the chest at any time, the cough cleared in three days, and the patient returned to duty in eleven days.

Pulmonary Lesions

Almost a quarter of all cases showed an involvement of a segment of one lobe only, usually of the right upper or right lower lobe. Only 4 of these cases presented a severe classical picture, which was most commonly seen when a whole lobe was involved. Cases of lobar and segmental distribution, however, showed many similarities, whereas those of "partial" distribution seemed to form a separate group. On the whole, cases with a lobar or segmental picture had a more sudden onset, tended to develop higher temperatures, resolved more often by crisis, and had higher white-cell counts. "Partial" and "central" pictures were associated much more frequently with cases classified as atypical or abortive.

Urinary chlorides were absent or diminished in three-quarters of the cases with a segmental picture; the proportion with reduced chlorides was greater among those with a lobar or segmental picture than among those with a partial or central picture, and much lower in the atypical group than in the other groups. This further suggests that primary atypical pneumonia exists as a clinical entity among West African soldiers.

Diagnosis

The diagnosis of primary atypical pneumonia is not always straightforward. Some writers emphasise the radiological appearances, but Stein and Kresky (1944) have shown that small wedge-shaped shadows and hazy diffuse mottlings are often seen in proved pneumococcal pneumonia and are not pathognomonic of atypical pneumonia. The American Commission (1944) reported that in only 31% of their cases was the titre of cold agglutinins high enough to differentiate atypical pneumonia from other respiratory diseases. As Joules (1943) says, some cases of atypical pneumonia may have similar signs and somewhat the same mode of onset as pneumococcal pneumonia, and often an accurate diagnosis cannot be made without radiological and laboratory investigation.

Of the 172 cases 118 (69%) were regarded clinically as of classical type, and of these 62 presented a very benign clinical picture. Correlation of clinical, bacteriological, pathological, and radiological findings shows that none of these cases could be regarded as variants of primary atypical pneumonia.

Type of Pneumonia Changing

It is recognised that pneumonia in England is milder than some thirty years ago. Reimann (1941) has noted the diminution in the death-rate from pneumonia in the U.S.A., and questions whether this is due to serotherapy and chemotherapy, or to a change in the disease. Is it possible that pneumonia is undergoing a cyclical change similar to that seen in scarlet fever?

The type of infecting agent may be a factor. In this series there were relatively few cases of proved pneumococcal infection. Some writers are of the opinion that the pneumococcus does not flourish in the tropics, and Leishman and Kelsall (1944) found very few cases of lobar pneumonia among a large number of patients in India. In the present series the incidence of *Strep. viridans* infection was unexpectedly high. Some cases may have been due to a primary virus infection with a secondary bacterial invasion, though they did not suggest this clinically.

In English children, after infancy, lobar pneumonia usually runs a favourable course, and the illness seen in the West African soldier is clinically somewhat similar. Bullowa and Gleich (1938) found that positive blood-cultures were obtained less often in children with pneumonia than in adults, and a higher proportion of cases with an upper-lobe involvement is found both in children and in West Africans than in English adults. The West African soldier is in many ways a simple person with a childlike outlook on life; perhaps his psychological make-up may play a part. Simpson (1944) comments on the rapidity with which his uneducated patients recovered. Ryle (1931, 1932, 1933) and others have revived interest in the study of "those differences between man and man, which are associated with, or concerned in maintaining a liability to or freedom from, some common forms of disease," and he is of opinion that "pneumonia or any other disease in an individual may be influenced in its course, not only by the type of the invading microbe, but also by the age and type of the patient, by his hereditary endowments, by his environment and by his psychology." In producing the benign type of pneumonia seen in West African soldiers all these factors may play their part; but environment, adequate diet, and early treatment are perhaps especially important.

SUMMARY AND CONCLUSIONS

Clinical, laboratory, and radiological findings in 172 cases of pneumonia among native troops in West Africa are described. About two-thirds of all cases were of classical or mild classical clinical type, and about a tenth "atypical," with a similar number of abortive cases.

The classical pneumonia had a benign clinical picture which resembles in many ways that encountered in children in England. Complications were rare, cure was early, and resolution was rapid. The average stay in hospital, including convalescence, was only 14 days.

Strep. viridans was almost as common as the pneumococcus as the causal organism and was usually associated with a mild classical picture.

Good general health, adequate nutrition, and early treatment under good conditions were factors of great importance in the production of a less serious form of pneumonia than that usually encountered among African civilians.

I wish to thank Major B. M. Wright, pathologist to the hospital, for his constant interest and help; Captain H. J. March, Captain G. C. Macdonald, and other officers of the medical division for their willing collaboration; Captain J. Yudkin for his keen coöperation in the preparation of a set of tables of correlations; and Major-General Sir Alexander Biggam, consulting physician to the Army, for permission to publish.

REABLEMENT OF CHILDREN WITH INFANTILE CEREBRAL PALSY

EIRENE COLLIS
C.P.T., M.C.S.P., M.A.O.T.
CEREBRAL PALSY THERAPIST, LONDON COUNTY COUNCIL

IE term "infantile cerebral palsy" covers the ous types of sensorimotor disabilities formerly ly called "spastic paralysis and allied conditions." term "spastic paralysis" is often a dual misnomer: astic" should be applied only to upper-motor-neurone ns with true spasticity; and in upper-motor-neurone ns the term "paralysis" is not strictly applicable. . the reablement of children with infantile cerebral y, paralysis is defined as inability to contract muscle he reason that the muscle is completely cut off from ous control. Cerebral palsy, on the other hand, is unction of movement due to a cerebral lesion interg with one or more of the several pathways directly erned with normal human movement.

pinion is divided about the efficacy of treating ntile cerebral palsy. Treatment may be non-operative g., massage, exercises, muscle stretching, electroapy, ultraviolet radiation, hydrotherapy, sedative gs, and splinting—or operative—e.g., tenectomies, tomies, neurectomies, nerve crushes, tendon splants, brain surgery, and cordotomies.

nly too often the child with infantile cerebral palsy ains a problem case. Many authorities think that current therapeutic measures need reconsideration, some say they are altogether useless. The educaty of these children is often questioned by teachers doctors in hospital and other schools; too many ept these children at their face value and agree with a dict of mental defect.

he outstanding characteristic of infantile cerebral sy is imperfect motor control due to cerebral damage icted on a growing organism. The appearance and aviour of these patients often lead to an incorrect gnosis and subsequent mistreatment of the child il he fits his diagnosis and becomes mentally and sically incompetent. Damage may, however, be so ht that it is undetected and motor disability passes clumsiness, laziness, or mild mental defect where handicap is "hidden"—e.g., athetosis of the raocular muscles, or partial deafness.

HISTORICAL

n 1941 I studied physical therapy under Prof. W. M. elps, of Baltimore, the pioneer specialist in the treatment of infantile cerebral palsy, at his Children's Rehabilitation Institute in Maryland. Professor Phelps emphasises the importance of classification of cases into one of five types (spastic, athetoid, ataxic, rigid, tremor) and the need for treatment of the child in a community by specially trained workers. For many years he has devoted himself entirely to the study and treatment of cerebral palsy, and he is recognised as the leading authority in this field in the United States. As a result of his work, many hitherto hopeless sufferers have been transformed into independent citizens.

I was so impressed with the work that I returned to England to seek research facilities and to rouse interest in this large group of handicapped children. No statistics are available in this country, but there is no reason to believe that the incidence of infantile cerebral palsy is less here than in America; where it has been estimated that 7 children are born each year with cerebral palsy in every 100,000 of the population. Of these 7, 1 dies in infancy, leaving 6 survivors, of whom 2 are feeble-minded and 4 educable. In a city with a population of 1,000,000 there will always be 700 educable children with cerebral palsy under the age of sixteen, distributed fairly evenly in urban and rural districts alike. The incidence is predictable and unlikely to decrease (Phelps 1946).

Owing to war-time difficulties it was at first only possible to form a small Parents' Club, the nucleus of the present British Council for the Welfare of Spastics (a regrettable title in view of the fact that recent American research shows that only 45% of cerebral-palsy patients are spastics).

In January, 1943, limited facilities were given for experiment with a small series of cases at Queen Mary's Hospital (L.C.C.), Carshalton, Surrey. The results obtained here in four years were so striking that the London County Council decided to expand the work to include children of pre-school and school age in suitable groups, and to re-form the existing unit into a research and diagnostic clinic dealing with all aspects of cerebral palsy. Though the experiment was severely hampered by war-time and other difficulties it has provided useful information.

In 1943 five children were treated; this number was trebled in 1944 and quadrupled in 1946. The first five cases treated were selected because of their former lack of response to treatment. Subsequent cases have been examined before admission to eliminate those with mental defect. Doubtful cases are reviewed during the three months' probation on which all children are brought into the unit. It has been decided to reject also cases complicated by operative intervention, epilepsy, or certain other conditions; and to reduce the age-limit to include a larger proportion of pre-school children. The cases are reviewed from time to time to assess progress-rates, and to decide on transfer to suitable schools as occasion arises. A number of children have been removed after a probationary period for reasons given above or because the diagnosis of cerebral palsy proved incorrect. Twenty have been retained for intensive treatment.

ILLUSTRATIVE CASE-RECORDS

Case 1.—A girl aged 15 in 1943.

History.—No details of pregnancy or birth remembered by mother. Patient had had "chorea since birth; mentality poor." Treated in various hospitals by orthodox physiotherapy and sedative drugs for years. Had once been sent home as untreatable, but later returned to institutional life (dates not available). No improvement in condition throughout these years.

On examination (January, 1943).—Appearance of mental defect, listless, unhappy, neglected, undersized, and underweight. Severe generalised athetosis, facial grimaces, continuous dribbling. Unable to sit securely on a chair, unable to kneel or to stand. Locomotion by shuffling on all fours

or with a walking-carriage. Able to feed herself to some extent, but threw food about; unable to drink unaided, dress, or care for herself. Speech laboured and indistinct; had not had speech training. Because she could not use her right hand she thought she was left-handed.

She was stated to have a peculiar body odour and to have violent fits of temper during which she bit, kicked, and scratched nurses; unfriendly with other children. She could not read or write, but made attempts to draw. Had been given lessons suited to a young mental defective, mainly handwork beyond her motor ability.

She was unwilling to coöperate in any new form of treatment, because she had suffered pain from muscle stretching and had been discouraged by lack of progress.

Deformities were due to severe tension, poor postural habit, and severe generalised athetosis (kypholordosis and bilateral calcaneovalgus). The deformity of both feet was said to be increasing.

She was allowed up for part of the day in a walking-carriage, but for the rest of the day was in bed with hospital restrainers on. She was taken by freighter transport to the massage department bi-weekly for walking exercises and muscle stretchings. She was not allowed to leave the ward except for treatment. Outside contacts were limited to staff and a bi-monthly visit from her mother.

During 1943 she remained under ward conditions, in a ward with some twenty chronically disabled and mentally defective children of various ages and types of neurological lesion; but by the end of that time she was permitted to leave off restrainers, fracture-boards on the bed, temperature-taking and use of the bedpan as a routine, and was permitted limited outdoor exercise and occasional excursions beyond the hospital gates. Drug treatment was given up in January, 1943, and visits to the massage department and use of walking-carriage and other apparatus discarded.

In 1944, when the cases for experimental training were selected, ward conditions were modified for the unit children within the limits of an institutional régime.

By 1946 further modification was permitted, and patient was given supervised employment in the new clinic.

By January, 1946, she walked on crutches with skis and was learning to use sticks, stood for an indefinite time unsupported, fed, dressed, bathed herself, and attended to her own toilet unaided, even when menstruating. She had no body odour.

She had learned to control deglutition and mastication, and there was no dribbling. She could drink unaided, perform tasks bimanually, and had made the shift from left to right hand dominance two years before. Speech, though affected, was usually intelligible to strangers.

In the supine and sitting positions there was no involuntary motion, and in the standing position very little. She could perform ballet exercises of the arms and trunk in the standing position and well-controlled rhythmic exercises in the lying, sitting, and kneeling positions.

She took meals at an ordinary table, seated upon an ordinary chair, using ordinary utensils; she slept in an ordinary bed in her own room, which she cleaned and kept tidy herself.

She had no deformities, wore no appliance, and had no drugs. In appearance she was attractive and clean. She read, wrote, painted, played in the rhythm band, could typewrite to some extent; she gardened and made knotted belts and dog-leads in her spare time. She enjoyed the cinema and could be taken out shopping or visiting.

In December, 1946, she showed slight regression owing to shortage of staff in the unit, but has since made excellent progress, particularly in the past 3 months, and she now walks unaided.

With continued treatment she should become employable under the Disabled Persons Act; but her age and hence long habit of faulty motor behaviour have prevented her from making greater progress, and lack of teaching has retarded her in school work.

The diagnosis of cerebral palsy of athetoid type with normal mentality has been confirmed.

Case 2.—A boy aged 12 in 1943.

History.—Normal birth. Normal progress until age of 7 years, when he had whooping-cough, followed by diphtheria, after which it was noted that he had increasing motor difficulty, including loss of speech.

Polioencephalitis, rheumatic chorea, spasticity, and postencephalitic parkinsonism had been diagnosed at various times.

Treatment at various hospitals had included that for rheumatic chorea, followed by that for a hopeless degenerating condition of postencephalitic type; sedative drugs; massage and exercises; and the application of various types of splints, a plaster bed, and a Clifford and Davis jacket.

Much deterioration in 1941 and 1942. Patient was to be sent home as a hopeless and progressive case in January, 1943, but he was given a final chance among the cases selected for experimental training.

He was up part of the day in a wheeled chair but had to be cared for in every way. His intelligence was said to be fair only, and he was afraid of any physical activity; he feared his right arm was permanently injured in a fall when he was aged 7 years; he knew that he had been given up by several doctors as a progressive case and he did not wish to try any further treatment.

He was listless and apathetic throughout the day, took two hours over a meal, food had to be pushed in through the side of his mouth by another child who sat beside him: his appetite was poor, and much food was spilled and wasted.

He slept badly in his plaster bed and had frequent night terrors. Unable to attend school because of complete helplessness and deformity.

On examination (January, 1943).—Helpless, thin, pale listless boy. Despondent mien. Nervous and sweated profusely during examination.

Continuous generalised athetosis, strong rotation of trunk and head and pelvis to right, strong flexion and torsion of trunk, right dorsal, left lumbar curve, asymmetry of buttocks, alteration of gluteal folds, left leg rotated out, dropped left foot, valgoid deformity, tibialis anticus tendon not palpable, no power in anterior tibial group. No use in either hand. Able to stand in a contorted position and to take a few sliding dipping steps, but tired easily.

Speech unintelligible and almost inaudible; closed eyes and grimaced violently on attempted phonation. Deglutition and control of tongue impaired. Breathing shallow and irregular. Unable to blow a whistle or sound the notes of a scale.

Treatment on new lines was begun in January, 1943, subject to the same limitations as those in case 1. Limitations were similarly decreased, and by 1946 he similarly lived a normal life in a self-contained unit and received treatment as a whole. He never wore the Clifford and Davis jacket made for him.

By January, 1946, he was a practising scout, attending outings and a summer holiday camp with normal boys; he could roller-skate, garden, kept rabbits, played in a rhythm band, could dance, run, and hop. He was the most athletic child in the unit and could turn somersaults, swing on the ropes by his hands, and was learning to ride a bicycle. He wore no splints of any kind.

He had slight residual disability of the right arm, but in spite of this achieved everything he undertook bimanually and he used his right hand for many acts, though not entirely for feeding or for writing and painting, but he was learning to paint with his right hand.

A report based on graphs kept from January, 1943, to January, 1945, runs as follows:

January, 1943	*January,* 1945
Walking	
Few slow shuffling steps at a time. Wheeled chair used. Much scoliosis and postural imbalance.	5 miles at an ordinary speed, up and down hill, runs at average speed, but with slight postural imbalance.
Relaxation, supine	
Not possible.	No involuntary motion during 10 min. Apart from the right arm, general relaxation maintained for 30 min.
Feeding	
Not possible, either hand. Takes about 2 hours over a meal because of facial athetosis and difficulty in opening mouth and in masticating.	Full meal in 30 min. Ordinary spoon and fork. Can drink with left hand. S yet a very tidy eater, competent and of appetite.
Speech	
Unintelligible, superimposed stammer. Said to have aphonia, but can make stammered sounds at times.	No stammer. Speech ally intelligible to staff, b less so to strangers, part because of self-consci ness under scrutiny

January, 1943	*January*, 1945
Typing	
been taught, but unsuccessfully; unable to use ands.	Types unaided, using both hands: apart from faulty spelling, typing is accurate and legible.
Domestic tasks	
possible.	In spite of residual disability of right arm, he achieves everything he undertakes.
Painting	
ng paint brush between eeth makes marks on paper.	This method was immediately discarded as psychologically unsatisfactory, and when he began painting again he had sufficient motor ability to use his left hand; he is talented and imaginative. Now using his right hand to a limited extent.

Similar records kept for other children show a similar gree of progress, but in this case startling improvent under intensive treatment was followed by considere regression when treatment was suspended owing to ffing difficulty. All cases have regressed in the past nths, but it is felt that renewed treatment will lead to ewed progress.

School work.—A special teacher is attached to the unit, l children of school age have ordinary lessons. Case 2 done well, but there are large gaps in his education, ause he had virtually no schooling between the age of nd 13. He is a voracious reader, fond of outdoor life, and inema addict. He is likely to become employable.

Social response.—Socially this boy, like all the other ldren in the unit, is acceptable; he has charming manners, ively and good-looking, with a healthy tan due to the fact t he spends much time out of doors.

In March, 1947, he showed marked regression, but the mbers of the Cerebral Palsy Committee were satisfied that s was temporary and due to old bad habit reasserting itself ring abeyance of regular treatment.

Final diagnosis of cerebral palsy of athetoid type with sion, and normal mentality.

Case 3.—A girl aged 4.

History.—Difficult birth. Asphyxia neonatorum. No king difficulty. No fits. No abnormality apparent to ther until child was aged 2 years and in the care of fosterents, to whom she had been removed because she had been lected by her own parents from the age of 9 months.

t 2 years she had been removed to a nursery, where she l been considered mentally defective. She had been dically examined and stated to be a case of spasticity with oördinate movements and mental defect. A further gnosis was "spasticity, abnormality of nervous system, ght be early progressive muscular atrophy."

n April, 1945, she had been recommended for institutional e as she was "gradually becoming more unstable in walking l even standing. Mentally alert child."

n September, 1945, she had been examined as a suspected e of Friedreich's ataxia.

n November, 1945, "spastic paraplegia with some ? microhaly, presumably a cortical development defect" had n diagnosed.

ater in the same month "? ataxy or athetosis with tension" l been diagnosed.

On examination (December, 1945).—Pale shy nervous with incoördinate movement and a stance resembling t of bilateral congenital dislocation of hip. No abnormality ected on radiography.

She walked with a lordotic gait on a wide base and with ch instability. She could not run, jump, or stand on ner leg. She had no idea how to play with toys, and use hands was limited by incoördination, but she could feed self.

She had fractured her right arm some months before in all and was apprehensive about using it, but she did not pear to be naturally left-handed. Speech was difficult to understand, but there appeared to be no true speech defect. Expression was furtive, with some dribbling and an open mouth.

A report was received that she was "a spastic with a sullen mentally defective appearance" and that she was "dirty, backward, clumsy, and intractable."

In December, 1946, after a year in the unit, visiting clinicians decided that the former diagnoses were mistaken. They could find no evidence of any neurological lesion and wished to discharge the child as normal. But as in another case in the series the parents had removed a child with athetosis as they were convinced she was "cured" and she had then regressed, the hospital authorities were asked to delay, for a few months, patient's discharge.

Owing to illness among the staff this child had received no specific treatment for some months. When her case was reviewed by the same panel of specialists, they found considerable evidence of athetoid instability, deterioration of gait, increase of facial athetosis, and renewed dribbling. They withdrew their former recommendation for her discharge and recorded the therapy finding of cerebral palsy, tension athetoid type, normal mentality. They recommended further treatment along the lines used between December, 1945, and July, 1946.

Patient now receives regular therapy to the extent permitted by staff shortage, and continues to make progress; she has again ceased to dribble, expression is happy, speech is normal. She has no deformities, and gait is steadily improving. In school she is slightly above the average for normal five-year-old children.

In these case-records note is made of facial appearance as it is often stated that children with cerebral palsy are unattractive in looks and behaviour. Where such children are being adequately treated by modern methods they present a pleasant and attractive appearance, do not dribble and grimace, and, as motor control develops, may reveal good looks formerly obscured by facial distortion.

The rest of the cases in this series have also made progress; no child has developed deformity since admission; and existing deformities have decreased or disappeared without recourse to usual hospital appliances.

It may, perhaps, be deduced that where selection is on a basis of mental competence, and where concomitant disabilities are not present, cases of cerebral palsy can be effectively treated, within the limits of present knowledge, by trained rehabilitation teams, and that treatment is most effective when begun at the earliest possible age—i.e., as soon after six months of age as a diagnosis can be made—and continued throughout childhood.

CLASSIFICATION

In the cerebral palsy unit a probationary period in each case led to reclassification in most cases, only two educable spastics being found among those presented as spastic diplegia or hemiplegia. The rest were educable athetoids. All were quadriplegics. Athetoids were found to be in excess of spastics in a proportion of 5 to 1. No true ataxias were discovered; those presented as ataxic were found to have athetosis.

It is therefore possible that very many cases of tension athetosis are at present classified as "spastic paralysis," and it may be that there is a preponderance of athetosis over spasticity generally in infantile cerebral palsy. It is also possible that most cases presumed to be mixed cases are tension athetoids, and many of the remainder may be spastics with apparent incoördination due to pyramidal involvement only.

Several children were transferred from the unit to institutions because of epilepsy, mental defect, and postoperative paralysis. Among cases reviewed 2 were seen with rigidity and tremor combined, and 3 were cases of mental defect with no motor disability due to dysfunction of the type describable as cerebral palsy.

After a preliminary examination by the cerebral palsy committee of the London County Council (now consisting of the medical superintendent of Queen Mary's Hospital for Children, four medical specialists, and myself) the child is given a probationary period in the unit to allow for classification and conditioning to environment, and to permit of some assessment of the mental potentialities of the child under review. Assessment of the total handicap, so far as present knowledge permits, is made as follows :

(1) Functional ability.
(2) Nutrition and appearance.
(3) Ætiology.
(4) Classification into one of five motor groups defined by Professor Phelps : spastic, athetoid, ataxic, rigid, tremor, or combined disability.
(5) Analysis of specific disabilities—e.g., muscle imbalance, joint motion difficulty, eye defect, hearing defect.
(6) Dominant handedness.
(7) Mentality, having regard to sensorimotor handicap and former environmental factors.

TRAINING

Training is instituted as follows, all measures overlapping to form a whole rehabilitation scheme :

(1) Physiotherapy.
(2) Everyday activities.
(3) Occupational therapy.
(4) Speech therapy.
(5) School or kindergarten work.

Physiotherapy includes the following measures :

(1) Functional examination, designed to discover the present ability of the child in ordinary life—e.g., ability to sit on a chair and to gain a standing position.
(2) Athetoid or spastic motor examination (according to classification) to discover the range of voluntary motion and control present, and the limitations imposed by the disability in respect of each part.
(3) Respiratory and deglutition training.
(4) Removal of faulty habit patterns.
(5) Establishment of correct motor patterns through trained motion according to analyses made.
(6) Balance—equilibration and muscle balance training.
(7) Voluntary postural correction.
(8) Special sense training.

Everyday activities consist of motion learnt in physiotherapy practically applied—e.g., hopping, ball-throwing, eurhythmy, and group work, such as rhythm band and games of all kinds.

Occupational therapy consists of movement learnt in physiotherapy applied to the use of material—e.g., self-feeding, dressing, brick-building, typewriting, and group work, such as gardening, care of animals, &c.

Speech therapy.—Speech training is based on movement learnt in physiotherapy applied to vocalisation and diction. Of course neither of these can be learned until respiratory difficulties, excess salivation, facial athetosis or spasticity, and tongue difficulties have been eliminated to some extent by physiotherapy.

School work.—Ordinary lessons are taught : learned movement is applied in school ; speech is practised in oral work.

Physiotherapy is based on the concept that in spasticity the lesion is pyramidal whereas in athetosis the lesion is extrapyramidal ; that damage to the cortex leads to a type of motor dysfunction which differs essentially from that due to basal damage ; that dual lesions are actually rare, though commonly children are thought to have a dual lesion ; and that tension athetosis is commonly diagnosed as spasticity.

Movement training is so directed that in each case substitution is effected for the damaged function. It is impossible to condense a description of therapy techniques or to elucidate the theories underlying these techniques in a paper of this length ; but for those interested a bibliography is appended, and the unit has always welcomed visits from members of the medical and ancillary professions.

Mechanical aids to training are introduced only to be discarded as progress is made ; these include "skis" for walking, individually adapted chairs and tables, wooden-handled spoons. Light splints or small springs are occasionally used temporarily in education of movement. Physiotherapy apparatus is simple and consists only of two ordinary tables, one set of webbing slings, one sloping board, and one ski-slide for walking. Occupational therapy equipment is that used in any kindergarten, plus a typewriter, a fretsaw, and gardening equipment.

Since the cerebral palsy unit at Queen Mary's Hospital for Children is primarily a diagnostic and research unit, education in school is carried on as part of the rehabilitation programme for children of school age during their stay in the unit. Children who had entered this unit at pre-school ages are now up to the normal standard in school work. Those who have had hospital treatment before admission to the unit are necessarily retarded in school for reasons of motor disability and consequent general retardation. In some cases these children have been enabled to "catch up" to normal; in others the age factor and long-established poor habit were against them. All have made progress consistent with increasing motor ability.

RESULTS

Owing to lack of provision of complete facilities and orthodox checking of results, it is impossible to offer final evidence other than the records and graphs kept between 1943 and 1946, the findings of the cerebral palsy committee, and the present condition of these children, formerly regarded as mentally affected spastic diplegics.

ADMINISTRATION

Since July, 1944, the cerebral palsy unit has been a separate entity so far as treatment is concerned; the children remain patients of the hospital but are housed in a separate building in the hospital grounds ; this block has been adequately equipped for twenty children. The London County Council intends to expand the work, using the present unit as the diagnostic centre, and providing for children of educable mentality in special schools after a period of intensive treatment in this unit. Medical supervision is at present in the hands of the medical superintendent of the hospital, Dr. C. D. Agassiz, and, since its inception on an experimental basis, treatment as a whole has been my responsibility. A part-time medical officer, a physiotherapist, an occupational therapist, a part-time speech therapist, a teacher, and a splintman have since been added to the staff and specially trained in the work. Care of the children is undertaken by a permanent staff of women orderlies supervised by a departmental sister.

The building was designed for two main wards of forty beds, and two day-rooms, enclosing on three sides a common courtyard. The two wings are now used as dormitory and dining- and school-room. The third side, which unites them, is divided into treatment rooms, with four small side wards two of which are separate bedrooms, one a speech-room, and the fourth an office. One former ward kitchen is still used for meal service, and the other is partly a store-room for tools, clay, and other equipment, and partly a common-room for orderlies.

Sanitary equipment includes low wash-basins and low lavatory seats with removable steps and arms for the younger children. Meals are served in the dining-room at a table for competent self-feeders, furnished with ordinary knives and forks and mugs, or at individual tables for learning self-feeders, who use a detachable wooden tray with slots for plate and mug and a wooden-handled spoon. Children who have still to be fed a separate tables in a row, so that one orderly can feed 'm all. Chairs fit each table and are adapted for each ld; steps and arms are used as long as they are ded. Similar chairs and tables are used for school rk. Children unable to walk are moved from place to ce in light wheeled chairs and are taken out daily; se who can walk go about freely in the playground. casionally an outing is arranged, or the children are ertained in the hospital building.

Routine is strict and allows $1^1/_2$ hours' individual rapy per child per week at present, and 2 hours h of group therapy. School work is limited to the nal terms but treatment is continued throughout the lidays, except where children are allowed to go home a short time. In the holidays much attention is paid outdoor games; see-saws, slides, swings are used, d there is a swimming-pool close by, where swimming taught. In fact, all activities commonly supposed to out of reach of children with cerebral palsy are ientifically taught to this group. The results have been riking in spite of staff-shortage and other handicaps.

CONCLUSIONS

Patients with cerebral palsy can be classified according the clinical manifestations, which can generally be rrelated with a presumed site of the lesion.

Owing to the complicated nature of the syndromes and e factors of growth, it may take time fully to observe e manifestations which differentiate the syndromes; at differentiation is simplified after a period of systematic aining in a special clinic. Training differs essentially r each type of motor disability.

In view of the facts that damage has been inflicted on growing organism and that the repercussions of this amage are widespread, treatment should be given early nd to the child as a whole, and preferably in suitable ommunities where all personnel are specially trained o work as a team.

I wish to thank Prof. M. F. Lucas Keene, Dr. Ruth Bowden, nd Prof. R. D. Lockhart for helpful criticism, and Mr. L. A. Key for advice and for permission to publish the cases described.

CONGENITAL ATRESIA OF THE ŒSOPHAGUS

TWO CASES SUCCESSFULLY TREATED BY ANASTOMOSIS

R. H. FRANKLIN
M.B. Lond., F.R.C.S.
SENIOR LECTURER IN SURGERY, BRITISH POSTGRADUATE MEDICAL SCHOOL, LONDON

THE two cases of œsophageal atresia with tracheo-œsophageal fistula reported below seem to be the first to be successfully treated in England.

In America Ladd (1944), Haight (1944a and b), Haight and Townsley (1943), Holt et al. (1946), Leven (1939, 1941), and Humphreys (1944) have notably contributed to the surgery of this condition and great success has attended their efforts.

Two factors have delayed progress in this country: the idea that the condition is extremely rare, and misconceptions about its nature. It is less rare than is usually supposed: 4 cases were found in 10,543 deliveries at the British Postgraduate Medical School, and Guthrie (1945), searching the records at the Royal Hospital for Sick Children, Glasgow, found 24 proved and a further 6 probable cases in 6916 necropsies.

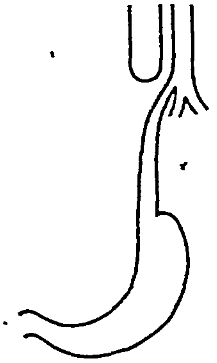

Fig. 1—Commonest type of congenital œsophageal atresia: upper œsophageal segment ends blindly at level of vena azygos arch; lower segment arises from trachea.

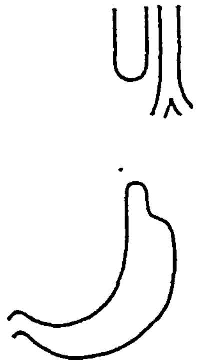

Fig. 2—Second commonest type of congenital œsophageal atresia: both segments end blindly, there being no fistula. Gap between segments may be large.

In the commonest type (80%) of congenital œsophageal atresia (fig. 1) the upper œsophageal segment ends blindly, and the lower segment arises from the back of the trachea, forming a tracheo-œsophageal fistula. In the next most common type (fig. 2) both segments of the œsophagus end blindly, and there may be a large gap between the segments. Very rarely there is a fistula between the upper segment and the trachea, or between both segments and the trachea. Still more rarely a fistula may exist without atresia. The cases here described were of the type shown in fig. 1.

Case 1.—A female infant, first child, born in Queen Charlotte's Hospital on Jan. 10, 1947, birth weight 7 lb. 7 oz., had attacks of cyanosis soon after birth, and attempts at feeding were followed immediately by cyanosis and choking.

The infant was seen by Prof. Alan Moncrieff, who made a tentative diagnosis of œsophageal atresia. No further feeding was attempted. The infant was transferred on Jan. 13 to Hammersmith Hospital, where the diagnosis was confirmed.

Confirmation of Diagnosis.—A soft rubber catheter was passed through the mouth and was arrested 10 cm. from the alveolar margin. Radioscopy showed that the lung fields were clear. Air was present in the stomach. Iodised oil, 1 c.cm., was introduced into the catheter and was seen to remain in the blind upper segment; the oil was then withdrawn. This examination confirmed the presence of atresia, and, by demonstrating air in the stomach, showed the type of anomaly. Care was taken to use only the smallest amount of iodised oil, so that none should spill over into the lungs.

Preoperative Management.—The blind upper segment was kept empty by frequent aspiration. The child's position was changed every quarter of an hour to allow each lung to expand. Dehydration was not noticeable, and no measures were instituted at this stage to introduce fluids.

Operation (Jan. 13).—The infant was secured in a prone position over a rubber water-bottle, the head turned to the right and a folded towel placed under the right shoulder. The line of the skin incision was infiltrated with 1% procaine. No other anæsthetic was used. Oxygen was given throughout the operation.

The incision started over the second right rib 1 cm. from the spine and passed downwards, curving slightly outwards at its lower end over the sixth rib; 2 cm. of the posterior part of the fifth rib was excised subperiosteally, great care being taken to avoid opening the pleura. The incision was carried upwards in the extrapleural plane, the intercostal bundles being ligated and divided, and the fourth, third, and second ribs divided. A small piece of the fourth rib was excised to improve the exposure.

The pleura was cautiously pushed inwards with a blunt dissector, and was inadvertently torn, but the hole was repaired by tying the edges together. The separation of the pleura was continued until the vena azygos arch came into view. This was divided between silk ligatures.

By gentle manipulation of the catheter the upper segment was identified, and stay sutures were introduced. The lower segment was found arising from the posterior surface of the trachea at the level of the azygos arch and was ligated and divided as close to the trachea as possible. Stay sutures were introduced into the lower segment.

Anastomosis was carried out with interrupted sutures of no. 0 silk. The lower segment was attached to the blind upper segment before the latter was opened; and, when the posterior part of the anastomosis had been completed, a catheter was gently pushed down from the mouth into the stomach and the anastomosis completed over the catheter.

At the end of the operation the catheter was withdrawn, and the wound was dusted with penicillin powder and closed round a rubber drainage-tube lying in the extrapleural space.

Postoperative Management.—The infant was placed in an oxygen tent, and the mediastinal drainage-tube was connected to a water-seal bottle. Nasopharyngeal aspiration continued. Position of infant changed systematically. Penicillin therapy started by intravenous drip set up in left leg.

Progress.—Jan. 14: condition excellent.

Jan. 15: good air-entry on both sides of chest; penicillin by mouth every hour; swelling and induration of left calf; drip set up in right leg.

Jan. 16: penicillin 4000 units hourly by mouth; saliva escaping round drainage-tube; much œdema and redness of right leg; drip taken down; rectal drip set up, 14,000 units hourly.

Jan. 18: infant passed a stool; no penicillin found in mediastinal fistula; radioscopy after introduction of a small quantity of iodised oil into nasopharynx showed that the oil entered the stomach; drainage-tube removed, and oral feeding started at noon: at 10.30 P.M. the dressing was moist and curds were present.

Jan. 19: infant very hungry; Kader Senn gastrostomy carried out (1% procaine) at noon; at 6 P.M. blood escaped from mediastinal wound on coughing.

Jan. 20: 1.30 P.M., child exsanguinated; blood-transfusion given. Condition much improved at 4 P.M.

During the next few days the chief concern was the varying amount of leakage from the mediastinal wound.

Jan. 28: no leakage of milk from chest wound; saliva still leaks.

Jan. 31: chest wound dry; gastrostomy tube removed; child started breast-feeding.

Feb. 17: child behaved normal except that Hb had fallen to 51%; ferrous sulphate given.

March 12: Hb returning to normal; child taking food well by mouth.

Case 2.—A female infant, second child delivered at St. Helier's Hospital on April 24, 1947, by cæsarean section by Miss M. D. Daley (disproportion had necessitated cæsarean section in the first pregnancy).

Birth weight 6 lb. 7 oz. Excessive mucus and slight cyanosis noted at birth; colour improved after pharyngeal aspiration. Saline by mouth produced a recurrence of symptoms, but one dose of penicillin is said to have been retained. A rubber catheter passed by mouth was arrested 10 cm. from the anterior alveolar margin.

Diagnosis was confirmed by radiography carried out as in case 1. Air demonstrated in stomach. In spite of care taken, some iodised oil regurgitated into lungs and these passed by an exceptionally large fistula into lower œsophageal segment and so into stomach. (This might lead to difficulty in diagnosis if screening were to be omitted and sole reliance placed on the radiogram.)

Operation (April 26).—Local anæsthetic. Posterior mediastinal extrapleural approach. Details of operation as in case 1. Anomaly found of type shown in fig. 1. Calibre of tracheo-œsophageal fistula almost as large as that of œsophagus. Œsophagus reconstructed as in case 1.

Postoperative Management.—A blood-transfusion (100 c.cm.) was started in the theatre and was followed by an intravenous drip of *N*/5 glucose saline. The rest of the postoperative management closely followed what had been carried out in case 1 and was in the hands of Dr. J. N. O'Reilly; but two improvements were made: (1) the penicillin was given by mouth 10,000 units hourly, starting when the infant was returned to the ward; and (2) the mediastinal drainage-tube was removed earlier (April 30). Before the tube was removed it was shown radiographically that iodised oil was passing down the reconstructed œsophagus into the stomach.

Feeds of expressed breast-milk were started on April 28. No leakage took place from the mediastinal wound at any time, consequently a gastrostomy was unnecessary. This fact made it possible for the infant to make a smooth convalescence, and the only complications were a Horner's syndrome and a slight ulnar palsy (both on the right side). The former cleared before the child left hospital.

When discharged on April 25 the child was taking breast feeds normally every four hours. Her progress has been maintained.

DISCUSSION

Early diagnosis is essential if success is to be obtained in these cases; to this end all babies with attacks of cyanosis and choking, made worse by attempts at feeding, must, until the contrary is proved, be regarded as having congenital œsophageal atresia. Meanwhile no feeding must be attempted. Unskilled attempts at diagnosis may lead to the contrast medium spilling over into the lungs. The proper method of diagnosis is described in detail.

As regards the operation, the extrapleural approach offers the best chance of success, because the suture line is almost certain to leak, and a leak within the pleura will almost inevitably kill the child. The use of penicillin greatly increases the chances of success.

The postoperative management is of the utmost importance, and without the coöperation of a skilled pædiatrician to take charge of the fluid requirements, and the unstinted services of an intelligent and conscientious nurse, the most careful operation will be of no avail.

I wish to thank Dr. Trevor Mann for looking after water balance and feeding after the operation; Prof. Alan Moncrieff for most helpful advice; and Sister Anderson and her staff nurse for their willing coöperation.

UDDEN DEATH FROM PERFORATED GASTRIC ULCER

S. SILVERMAN
M.D. Leeds

ASES of immediate death from the perforation of a rio ulcer seem to be rare. Hurst and Stewart (1929) ed that "in exceptional cases the agony caused by perforation is so overwhelming, and its effect on the ulation and nervous system so great, that it has sed sudden and immediate death; and in other es, though not immediate, death occurs before signs peritonitis have developed." Moynihan (1901) found erforation of the duodenum just beyond the pylorus a case of sudden death, the relatives affirming that patient had never had *any gastric or intestinal* ease. Simpson (1936), in a very extensive experience autopsies on cases of sudden death, only recalls two ilar cases, one of which was that of a man, aged 32, o collapsed and died in the street; a very recent foration of an acute duodenal ulcer was found post rtem, and although the peritoneal sac was full of bile-ined duodenal contents, there was no peritonitis. The ht heart was widely dilated, the left firmly contracted. ere was no other disease.

Moynihan (1928) stated that not one of the signs of ock (increased pulse-rate, diminished blood-pressure, luced blood volume) may be present within an hour two of perforation, and that prostration was a more itable term for the condition found. McCreery (1938) mmented on the relative infrequency of shock in ese cases. The systolic blood-pressure was below 0 mm. Hg in only 1 of the 63 of his cases that covered, and in 7 of 19 fatal cases. Eliason and beling (1934) stated that in only 4 of 46 cases was the stolic pressure below 100 mm. Hg. Soutter (1941) id that only 6% of 335 cases had classical symptoms of ock. He found no definite relation between the degree shock and the size of the perforation or the amount fluid in the peritoneal cavity. In the following case dden death followed the perforation of an ulcer on e lesser curvature of the stomach.

CASE-RECORD

A tube-finisher, aged 45, who had been an outdoor labourer til three years earlier, had had gastric trouble for some ears, not serious enough to interfere with his work. Epi-stric pain came on about an hour after food, lasted about lf an hour or less, and was relieved by alkaline powder. adiography on Aug. 11, 1942, revealed an ulcer of the lesser rvature, the gastric emptying time being four hours. He as put on a restricted diet but continued at his work as efore.

On the morning of Sept. 16 he complained of pain in the pper part of his chest at the back, and later at work he ad a feeling of oppression in the chest. However, he worked roughout the day as usual and partook of his usual meals t 10.30 A.M. and 12.30 P.M., both of which consisted of eamed fish, white sauce, butter, and milk. He had a cup of a and some biscuits at 4 P.M. and returned home at 8.45 P.M., ormal and apparently cheerful. He took a dose of alkaline owder, as was his custom. He then had occasion to reprove nd punish his young son and was very much emotionally pset later on at finding himself in error for doing so. He hen became short of breath and was tapping his chest with he flat of his hands and complained of a pain over the right capula. He retched but did not vomit, then sat down and it a cigarette. He seemed comfortable and went upstairs at 0.20 P.M., where he undressed, wound up his watch, put out is cigarette, and went to bed. Shortly afterwards his wife eard him moaning. She found him with his arms and legs xtended and his hands clenched. His face was deathly pale, and he repeatedly blinked his eyelids. He gasped but ould not speak; but, asked where his pain was, pointed to he lower part of the sternum. He died at 10.35 P.M.

Post-mortem Findings.—Necropsy was performed next day. here was no food, blood, or free fluid recognisable in the peritoneal cavity, and no sign of peritoneal irritation or inflammation. The stomach was large and contained a moderate amount of milky white fluid. There was a simple obviously chronic ulcer on the anterior surface, close to the lesser curvature, midway between the œsophageal opening and the pylorus. The ulcer crater was $^1/_2$ in. deep and 1 in. wide. There was an oval perforation, 4 mm. long and 2 mm. wide, through the floor of the ulcer into the main peritoneal cavity. There were some local peritoneal and omental adhesions. The gall-bladder also was bound down by adhesions.

There was evidence that the heart had stopped in a systolic phase, and no blood was present in the left ventricle. No defect was found in the coronary arteries or their branches apart from slight atheroma; the myocardium and the cardiac structure appeared normal. There was some atheroma of the descending aorta, especially near its bifurcation. There was no macroscopic abnormality of the kidneys and endocrine system, including the suprarenals. There was a small diverticulum of the urinary bladder. The intestinal tract, peritoneum, and brain appeared normal.

COMMENTS

Death apparently took place almost immediately after the perforation of a gastric ulcer and before any signs of peritonitis had time to develop. It is not clear exactly how the termination, in such a case, is brought about. It is known that mechanical irritation or accidental section of the vagus nerve in the neck can cause sudden death, attributed to inhibition of the action of the heart. It is also possible that exhaustion of the hypothalamus, such as might result from an emotional upheaval, followed by perforation of the ulcer, as in this case, might lead to uncontrolled vagal inhibition and sudden death.

Gas embolism as the cause of sudden death is unlikely, since the gas would have to enter the systemic circulation, and examination of the lungs excluded this.

Widal et al. (1920) produced in dogs sudden death from "hæmoclastic crisis" by injecting autolytic products of protein digestion into the general circulation, but the absence of food or fluid in the peritoneal cavity in the present case rules out such a happening.

I am indebted to Dr. A. V. Neale, physician to the Birmingham United Hospital, who performed the necropsy, for the following comment:

> "There seems to be no doubt, from the clinical sequence of events and the necropsy findings, that this man died very rapidly as a direct result of the ulcer perforation. There were no indications of any other important structural disease. The mode of death suggests a rapid exhaustion of the neuro-circulatory mechanisms, as a final response to the violent and sustained pain of the perforation. Vagus reflex inhibitory influences may have played some part in this adverse reaction. The total circumstances, mental and physical, in a catastrophe of this kind have to be summed up in arriving at possible reasons for rapid death. An emotional storm, as in the present case, though subsiding somewhat, may be a relevant factor in increasing the susceptibility. There are points in the present case directing towards this view."

". . . Public health research of earlier days was often concerned with the minimum conditions necessary to ward off disease and preserve health. . . . Now . . . we are travelling away from the nicely-calculated more-or-less-ness of minima, towards the more liberal view of optima for the preservation and enhancement of health."—Dr. J. L. BURN, *Recent Advance in Public Health*, London, 1947, p. 1.

Reviews of Books

Animal Genetics and Medicine

HANS GRÜNEBERG, PH.D., M.D., reader in genetics, University College, London. With a foreword by Sir HENRY DALE, O.M. London: H. Hamilton. 1947. Pp. xii + 296. 21*s*.

IN human genetics people too often assume, once it has been established that a disease is due to a particular gene—dominant, recessive, or sex-linked—that there is no more to be said. Dr. Grüneberg's account of animal genetics, though confined to rodents, indicates how far from being correct is this narrow viewpoint. Inherited disease is as dynamic a process as any other type of disease. The gene is a substance, whose action is not magical but which produces an end-result by means of concrete physiological and pathological mechanisms. These mechanisms can be closely studied in animals, where both gene and environment can be purified to a degree unthinkable in the case of human subjects. The obvious disadvantage of insect material —that the experimental organism is so unlike man— does not apply so strongly to rodents. The medical reader of this book will be astonished to find how many hereditary or partly hereditary conditions and diseases known in man are paralleled in other mammals. Spastic paralysis, ataxia, acholuric jaundice, microphthalmia, polydactyly, diabetes, and harelip are just a few examples. Even epilepsy occurs in rodents. The Viennese white rabbit is liable to spontaneous major attacks, and these and other animals with inherited epileptic diathesis have a lowered threshold to 'Cardiazol.' Certain mice are thrown into convulsions by sound and others similarly affected by odours.

The essence of Dr. Grüneberg's presentation, however, is not so much to point out parallels as to establish the system of cause and effect which has been initiated by each gene. This treatment lays bare fascinating networks of pathological events; in tracing the multiple effects seen, for example, in the grey lethal or the hydrocephalic mouse, it rivals any study of crime in fact or fiction. Moreover, the discovery of red cells containing "free" iron (siderocytes) in flexed-tail anæmic mice has had a direct bearing on the diagnosis of anæmias in man. The accounts of hereditary variation in immunity to infections, though brief, are stimulating to the imagination. At the same time, the student who reads the book is never in danger of being misled by speculative discussion. The known facts are always stated in the clearest language and distinguished from the author's own inferences or those of other workers. No attempt is made to conceal the numerous points on which information is inadequate, however uncomfortable this may be as regards satisfactory theory. The "pedigree of causes," which it is the aim of the method to establish for each condition, is almost always incomplete. As the writer himself points out, the analyses which can be made on existing embryological, histological, and clinical evidence are usually at the mechanical level rather than at the more fundamental chemical level. Such analysis is, however, the first step, which must be taken; and in taking it Dr. Grüneberg is doing for the pathology of genetically determined diseases what Virchow did for pathology in general. The happy circumstance that he himself has not only contributed very substantially to our present knowledge of rodent genetics but is also a clinician and a pathologist has enabled him to present the new field of investigation so well that the book should become a medical classic.

Insect Pests

(2nd ed.) W. CLUNIE HARVEY, M.D., D.P.H.; HARRY HILL, F.R.SAN.I., A.M.I.S.E. London: H. K. Lewis. 1947. Pp. 347. 14*s*.

THIS handbook, dealing with the insect pests liable to infest British people or their dwellings, is designed for regular reference by the practical hygiene official. The chapters on procedure and legislative control, as well as that on building construction and infestation, are comprehensive, and are no doubt based on the solid experience of the authors. The sections dealing with control measures are generally good, though it is surprising to find no description of controlled tipping, or the management of refuse-tips to control infestations by flies and crickets. The hot-air disinfestors, which were so useful to disinfest bundles from air-raid shelters during the war, are not mentioned, and there are also lacunæ in the biological data: for example, a section on the bed-bug which goes into anatomical details of the organ of Berlese should not omit the useful information on bug biology summarised in the Medical Research Council report of 1942. Data on speed of development of the bug and its resistance to starvation under different climatic conditions are of practical importance. A number of misprints in the specific names of insects should not have crept into a second edition. Two new chapters, on mosquitoes and on new insecticides, are useful, and where the specific uses of new insecticides are given, the advice is sound; but several out-of-date methods should have been relegated to second place or dropped altogether: for example, the elaborate method of bug-disinfestation by use of heavy naphtha should be superseded by the much simpler and more reliable use of D.D.T. spray. No mention is made of lethane hair oil for use against head lice, nor of benzyl benzoate emulsion for scabies, though both were added to the *National War Formulary* in recent years.

Treatment of Diabetes Mellitus

(8th ed.) ELLIOTT P. JOSLIN, M.D.; HOWARD F. ROOT, M.D.; PRISCILLA WHITE, M.D.; ALEXANDER MARBLE, M.D.; C. CABELL BAILEY, M.D. London: H. Kimpton. 1947. Pp. 861. 50*s*.

WE welcome the new edition of this book not only because it brings the Boston school's thoughts on the subject up to date, but because it gives us most of the references new and old on this wide subject. For this reason alone everybody seriously interested in diabetes and carbohydrate metabolism must have it; and the covers and binding hardly seem strong enough for the hard reference work the book will meet. The indefatigable work of Joslin and his group is so highly valued, and their ideas are so often ahead of accepted facts, that criticism of their book may be offered almost appreciatively. One edition stated that diabetes starts and ends with obesity as a cause, another that diabetes is a recessive mendelian hereditary disease; but this edition seems to have retracted its statistical dogmatism on these points. A new and interesting suggestion is that "hormonal imbalance" is the chief cause of the high prenatal and neonatal death-rate in the babies of diabetic mothers. The authors claim that such disasters can be prevented by giving the diabetic mother very large doses of œstrogen (stilbœstrol) and progesterone, the former being the more important.

The Principles and Practice of Medicine

Originally written by WILLIAM OSLER, M.D., F.R.C.P. (16th ed.) H. A. CHRISTIAN, A.M., M.D.; LL.D., HON. SC.D., HON. F.R.C.P.C., F.A.C.P., Hersey professor of the theory and practice of physic, emeritus, Harvard University. New York: D. Appleton-Century Co. 1947. Pp. 15[illegible]. $10·00.

ACCOMPANYING the 16th edition of this famous textbook is a short history of medicine as it has developed since Osler brought out his first edition in 1892—a story of remarkable progress. Professor Christian has retained the personal touch for which "Osler" has always been famous, while bringing the book up to date. Penicillin and the sulphonamides are here in full; tridione is mentioned in the treatment of petit-mal, and streptomycin for tuberculosis (though not for leprosy). Psychosomatic medicine was recognised in the last edition (1942), but surely by now deserves more than a page and a half. Medical facts of historical interest which have helped to make the book so popular, are still here: for example, the researches carried out on acclimatisation by Haldane, Douglas, and Henderson on Pike's Peak. The references at the end of each chapter might conveniently be put in alphabetical order. The last seven pages are devoted to those normal laboratory values of blood, plasma, and serum which sooner or later everyone forgets. Taking it all round "Osler" remains the ideal bedside medical textbook.

Anginal Pain

In view of the now generally accepted theory that the pain of Angina Pectoris is due to myocardial anoxaemia, a potent coronary vasodilator, such as Cardophylin, may be of value in relieving the anoxaemia when that is due to an inadequate blood supply to the myocardium, especially where coronary constriction is the main factor in interfering with the blood supply.

Cardophylin

A SPECIALLY PREPARED COMPOUND OF THEOPHYLLINE-ETHYLENEDIAMINE

INDICATIONS:

ANGINA PECTORIS
CHEYNE-STOKES RESPIRATION
PAROXYSMAL NOCTURNAL DYSPNOEA
CARDIAC ASTHMA. OEDEMA.

LITERATURE AND SAMPLES ON REQUEST.

IN TABLETS OF 0.1g FOR ORAL USE.
AMPOULES FOR INTRAMUSCULAR INJECTION 0.48g. IN 2 CCs
AMPOULES FOR INTRAVENOUS INJECTION 0.24g. IN 10 CC.
SUPPOSITORIES EACH CONTAINING 0.36g

When **superficial pain** is the problem . . .

Pain and pruritus are common denominators of so many everyday accidents and affections . . . a pointer to the wide scope for 'Anethaine' Ointment in general practice. Minor burns, anal fissures, insect stings and most skin diseases are conditions in which 'Anethaine' Ointment brings welcome and rapid analgesia. The ointment is particularly effective in relieving the extreme discomfort of haemorrhoids and may be safely prescribed for the patient's personal application.

'Anethaine' Ointment is of the 'non-greasy' type and contains 1 per cent amethocaine; applied to the skin or mucous membrane, it is effective within a few minutes and maintains analgesia for at least two hours. 'Anethaine' Ointment is clean and pleasant to use and is easily washed off the skin or clothing.

GLAXO

ANETHAINE OINTMENT

(Brand of Amethocaine) in ½ oz. tubes

Nutritional safety

during weaning

As the infant's introduction to solid food, and as a basis of the diet during the subsequent months, there is no more suitable preparation than Farex. The usual starchy predominance of cereals is balanced in Farex by an increased proportion of protein: in addition, Farex supplies minerals — assimilable iron, calcium and phosphorus — and a useful amount of vitamin D (1,000 i.u. per oz.). With Farex and milk as the staple ingredients, weaning to solids is reduced to its simplest and safest terms. Please help to ensure sufficient Farex for weanlings by prescribing it only for them.

Readjustment

A PATIENT comes to his doctor in a state of mild rvous breakdown. He is finding the day-to-day nagement of his life increasingly difficult. No gan system is unhealthy, but his capacity for aptation to the demands of his environment and his inner needs is inadequate; there is a breakwn affecting the person as a whole vis-à-vis e environment as a whole. In such a case the tient's inability to meet the current requirements work and adaptation can generally be traced to version of part of his energies to the solution of solved emotional or personal problems of the past problems by no means extinct but living on into e present, usually well below the level of conscious areness. On the surface there seems to be no ason why, with all his apparent health and good will, e patient cannot make a success of his life. He is ready to start again," to start with a clean slate. ut Nature provides the sponge only for those who ve finished their tasks. It may be impossible to store a working equilibrium unless each of the sues once shirked is faced again, the reason for the ast evasions is examined, and the old struggles are lived (but with clearer insight) till the gaps in ast experience are closed and his life in the present unencumbered by the pressure of old conflicts. n all this the doctor's function is to be not only n analyst of the forces, cohesive and disruptive, ithin the patient's mind, but also to be the catalyst a new synthesis.

Today, in our body politic, no one "system," ade, or industry is manifestly disordered, but their teraction as one whole is unsatisfactory. On supercial viewing there is enough energy to meet all urrent requirements; but something is lacking n coördination or morale. Computations of manower or horse-power are no true index of potentiality: n the coal industry, for example, failure to act on the commendations of the Sankey Commission after e first world war created a gap between expectation nd fulfilment—a sense of frustration—which pereates the situation today. Time, says the psychonalyst, never heals; procrastination is not a theraeutic agent; and it is not an act of political wisdom o ask any man to forget the past. Similarly, in nternational as well as national relations unmeasurble elements have to be given their importance if e are to readjust our values, and redeploy our forces, n this our latest malaise.

One of the great (but little sung) benefits of war is hat the community is given an object, the enemy, n which aggression may be turned with an easy onscience. The group-disruptive forces, which are lways present—is not a mixture of love and hate for the same object our most human characteristic? —thus find to a large extent a temporary approved outlet. To try to recapture "the Dunkirk spirit" without providing a threatening enemy at the doorstep is to attempt the impossible; for the problem is different. The threat now is not so much external as internal; and we face only with great reluctance the need to reorganise our way of living sufficiently to make our social and economic metabolism balance. Just as the individual dreads to face the disruptive forces within himself, so the community now dreads to face the social aggression and economic chaos which it fears is imminent. It is highly unlikely that such a danger is actually near, but the anxiety about it is present just the same. Our British way of adjustment and compromise rejects either extreme measures or short cuts; our political experience and the faith we repose in each other leads us to believe that it will be unnecessary for us either to be swept into the Russian orbit or become a cat's-paw of American big business. But time is short, adjustment is always slow, and we always fear the worst, not least while denying its possibility.

Each of us responds to the national difficulties in his own way. Some feel threatened by any change at all; a very few regard any change, however tumultuous, with indifference or amusement; the majority are affected, though by different aspects of the same thing. A crisis exists when everyone, except the queer people at either extreme, believes that a change beyond anyone's control will occur. A crisis does not exist if changes, however great, are unobserved, or if there is a strong belief that the pattern of equilibrium will right itself, or if the changes can be controlled by forces or institutions or people who are trusted. Where morale is high, adaptability is also high: and if a high degree of adaptability can be achieved the danger-point will nearly always be passed in safety. To judge whether there is a "crisis" on us now we may ask what is the state of our morale, our capacity for mutual trust, our belief in a common purpose, our tolerance of differences, and our readiness to accept changes, if need be, in the pattern of our lives.

If we are all in this together, who is to be the therapist to resolve our difficulties? Are the blind to lead the blind? Do we not need a leader whose clarion calls will rally the nation, a powerful will to overrule the obstructive, a man of blameless record on whom all can rely? (How reminiscent are these pleading wishes of the sufferer in his individual crisis who desires as a helper the biggest name in the profession, or to be told what to do, or someone he can "really" trust.) How, more rationally, can we find an outside helper, a catalyst and synthesiser, who stands calmly above the battle? If the only analogue known to medicine were that of individual therapy the question would be hard to answer. But the past few years have seen developments in another technique in which the study of the intra-group tensions is made the task, the therapeutic task, of the group itself. Here the disruptive forces tending to break up the group are given at least as much consideration as those which lead to group coherence, and the members get from the discussion only as much as they put into it. In group therapy of this kind, the rôle of the doctor is not that of an adviser but of a "clarifier": the patients' appeals to him for guidance, their looking to him for leadership, are signs of temporary mutual distrust. His most effective power is shown, or his impotence most clearly displayed, in his handling of the hostile demands for action at a time when action is inappropriate. His skill lies not in persuading them to follow a course of action but examining *with* them—for he is a member of the group—the reason why they are blocked from achieving their goals. Today, instead of asking for a leader, we should be recognising that part of the duty of analysis, clarification, and catalysis devolves on each one of us; we must not pass on any burden of thought, responsibility, or courage that we can carry ourselves. The Government must inevitably function as the chief clarifier, but it cannot do this if the public does not want the issues to be clear.

Gonorrhœa in General Practice

GONORRHŒA is one of those problem diseases which the practitioner has always regarded rather warily. He has recognised that it is resistant to treatment, that its cure is hard to determine, and that it may have serious consequences for the individual, the family, and the public health. Formerly, therefore, he was content to send the patient straight to a specialist and to limit his own rôle to help in adjusting family difficulties. In the days when the sulphonamide drugs seemed to lessen the difficulty he became much more inclined to "have a go"; but, while rejoicing in apparent successes, he quickly passed the failures on for expert advice. Since penicillin has been obtainable there has been a further change of outlook, and the practitioner is tending more and more to treat gonorrhœa, at any rate in the male. This may prove an advantage to the patient, provided certain standards are maintained and certain responsibilities are recognised and accepted. The drug is easily administered, safe, and effective. Where, then, do any dangers lie?

First is the question of diagnosis. It is still not universally appreciated that there are common causes of urethritis other than the gonococcus, and that most of them are not susceptible to penicillin treatment. If penicillin is given without a preliminary microscopical test the diagnosis may always remain in doubt; and accurate diagnosis is essential both for successful treatment and as a guide to the right course to adopt in investigating and treating contacts, both inside and outside the family. Next comes the question of dosage. With so safe a drug it is tempting to overwhelm the gonococcus with a massive initial dose. The difficulty is, of course, that syphilis is often contracted at the same time as the gonorrhœa, and syphilis has a longer incubation period. Even small doses of penicillin can prolong the incubation period of syphilis, or mask the early stages of the disease, and larger doses, if they do not entirely destroy the infection, will increase this danger. Dosage should therefore be limited to the minimum which will give a high proportion of successes.

After treatment cure must be established. With penicillin prompt cessation of symptoms and signs is the rule; but it may be deceptive, for gonorrhœa is notorious for its tendency to infectious latency. A period of close observation and a series of careful tests are essential before cure can be presumed. Most of these tests are matters for the expert, but with male patients there is a simple one which is within the scope of the practitioner and may indicate in good time the desirability of further advice. Symptomless carriers of infection are often free from signs at most times of the day, but examination of the first morning specimen of urine, held for at least eight hours and recently passed, is likely to yield evidence of infection obvious to the naked eye in the form of threads, haziness, or turbidity. Such a test should be repeated several times. That cure should not be presumed easily or lightly is evident from the co experience that relapse in the symptomless patient may come weeks or months after apparently successful treatment. Clinically these cases cannot be distinguished from those due to reinfection, but the sequence of events has been observed so often in patients whose histories seem reliable that the fact of genuine relapses must be accepted. In the female diagnosis and the determination of cure are considerably more difficult, and require specialised aids, such as a good culture medium, which practitioners seldom have at hand.

Already there is reason to think that these simple rules are not being observed. Sometimes patients with urethritis arrive at hospital for diagnosis after having had anything up to 3 mega units of penicillin from their doctors; and there *must* be other cases in which this attempt at confirmation is not made at all. There is some fear too that the greater use of penicillin by mouth may add to the confusion of a dangerous situation. Oral penicillin is less certain in its action, and the appropriate dosage is more difficult to estimate: the patient must coöperate strictly in taking the right doses at the right time, and the standards of tests for cure must be very high. If we allow ourselves to be misled by the ease and simplicity of this form of treatment the result will be a legacy of latent infection with all its crippling after-effects; and it is only too likely that we shall breed and foster lusty strains of penicillin-resistant gonococci.

Cerebral Palsy in Children

THE idea that congenital and acquired cerebral palsy can be treated is still new enough to be startling. The work of Dr. WINTHROP M. PHELPS in America, the example of Dr. E. R. CARLSON (himself a cerebral diplegic), and the founding of schools at Croydon[1] and Birmingham[2] for affected children, and of hospital clinics for their treatment, all testify to a live interest in this subject. The newly formed British Council for the Welfare of Spastics and the Scottish Council for the Care of Spastics are planning programmes of research and courses of training for therapists and teachers, and the Ministry of Education[3] is supporting an appeal of the B.C.W.S. to local education authorities for financial contributions.

[2] *Ibid*, 1947, i, 108.
[3] *Ibid*, Aug. 9, p. 230.

Some of the best work of the kind has been done
the London County Council cerebral palsy unit
Queen Mary's Hospital, Carshalton, since January,
3. Here, with makeshift and limited equipment
l dowdy though roomy quarters, Mrs. EIRENE
LIS is making studies of muscle action, and
ting good results in the treatment of a group
diplegic children. On p. 239 she describes some
her results. She classfies cases under two main
ds: as spastic, where the lesion is mainly pyra-
lal, and as athetoid, where the lesion is mainly in
basal ganglia. There are also ataxic cases in which
lesion is cerebellar. Mixed cases, it seems, are
, and in practice it can be assumed that a child
h athetosis has no true spasticity: his apparent
sticity is of psychological origin, deriving from his
empt to control the athetosis; and the child can
rcome it. He is first taught to relax—to lie
npletely at physiological rest for a longer and
ger period at each session. He then learns accurate
poseful movement, not merely as a form of play
rapy or as a side-line to occupational pursuits
ough these may be used too), but as a serious study
which he is expected to work. The atmosphere of
k and attention in the treatment room helps the
ld to develop his character and sense of responsi-
ty. Nor are things made particularly easy for him;
is not told "Lift your arm"—a thing he does
ry day of his life and takes as a matter of course—
"Abduct your arm," a technical term which
s the movement in a different and more important
it. He learns incidentally to his treatment the main
scles by name, and responds to requests in which
y are so mentioned. This calls for at least average
elligence in the child; and children with cerebral
sy are in fact nearly always normal mentally.
leed, if a child, whether athetoid or spastic, proves
apable of benefiting by sustained adequate treat-
nt this is generally evidence, Mrs COLLIS finds, of
ntal defect. The younger children of course,
not follow such complex patterns as the older
ldren, but they early learn to think of the
atment room as a place of work and study.
e playroom is different, with its own informal
nosphere.

The spastic child differs considerably from the
etoid; his spasm is pyramidal in origin, and he
not relax it; no amount of training in relaxation
l help him to lengthen a spastic muscle. His
iculty must be approached in another way. In
movement, the prime mover of a joint is a muscle
ing against gravity or against resistance. Thus in
ordinary position of the arm the biceps is the
me mover of the elbow-joint. In the spastic child
tense biceps cannot lengthen steadily and easily
order to let the triceps straighten the elbow; but
e the arm above the head and the situation is
nged: the triceps is now the prime mover, acting
inst gravity, while the biceps becomes the synergist,
l it is now found that the child can easily straighten
arm. In other words, the biceps when acting as a
ergist loses its spasm; for, as WOOD JONES[4] has
nted out, we cannot by taking thought alter the
scle sequence in a movement. Once the prime
mover acts the synergists fall into their pattern and accompany its movements by changing length appropriately. The task, then, with the spastic child, is to teach him the feel of his muscles when they are acting without spasm: to give him a "kinæsthetic image" of the perfect movement. Once this has been achieved the child himself develops the idea—he learns to perform the same movements with the muscle in the ordinary anti-gravity position.

Mrs. COLLIS has a simple device for reversing the effect of gravity: she places the child head downwards on rather a steep inclined plane, and tells him to let his arms hang above his head. In this position all the usual prime movers take their place as synergists: the latissimus dorsi and biceps lengthen, the legs fall apart by their own weight, the gastrocnemius lengthens in favour of the tibialis anticus; and the child is able to learn movements long denied him.

It requires attention on the child's part to perform these movements and to translate them into their counterparts in the upright position; and it is thus not surprising that if treatment is interrupted the child's progress is hindered, and he deteriorates. A pianist maintains his virtuosity only by constant and regular practice, particularly in the early stages. The adult spastic who has worked hard at overcoming his disability is able to maintain his standard because he has the necessary knowledge and responsibility, quite apart from the years of practice behind him; but similar qualities cannot be expected of a child. It is thus the more unfortunate that the L.C.C. cerebral palsy unit is at present handicapped by lack of adequate staff, both trained and untrained.

The subject is intricate, and calls for a careful study of individual movements. At the unit a chart for the examination of spastics covers 74 muscles, which must be noted as normal, spastic, or flaccid; while a joint-motion chart for athetoids covers 86 movements.[5] Exercise is planned to meet the findings in individual children, and is based on analyses of normal movements. From this unit, which is mainly for research, older children will shortly be handed on to appropriate schools after diagnosis, classification, and a comparatively short period of intensive training; the chief aim of the unit is to provide for the preschool child before he can acquire deformities and bizarre behaviour patterns.

Ordinary school lessons are given to the school-age children daily in between time by a qualified teacher specially trained in the unit, and it is noteworthy that the behaviour of the children both at school and at play is much more like that of normal children than is that of the usual "hospitalised" child. They do not freeze into dumb politeness before a visitor, and they are pleasantly boisterous with one another: the atmosphere is not that of a ward, nor are the children encouraged to think of themselves as patients; they are a group of school and preschool children working to overcome a disability while pursuing their ordinary studies. This is the spirit which should be encouraged in all wards where children are gathered for long-term treatment.

Vood Jones, F., Porteus, S. D. Matrix of the Mind, Honolulu, 1928.

[5] Routine work is set out in Mrs. Collis's book: A Way of Life for the Handicapped Child. London: Faber & Faber. 1947. Pp. 183. 10s. 6d.

Annotations

TEMPORARY REGISTER

LAST week we summarised the Bill by which the Government propose next session to regularise the position of doctors holding Colonial or foreign qualifications, who have been temporarily registered by the General Medical Council, or have served in the British Armed Forces, or have entered this country through circumstances of war. Since 1940 temporary registration has permitted refugee doctors to work in this country in hospitals or as assistants, though not as independent practitioners; but unless fresh action is taken this permission will lapse at the end of the year. The number who may be expected to seek permanent registration is less than 2000, and many are elderly people. While refugees could not expect any arrangements to be made which in the post-war search for appointments would place them in a better position than their British colleagues retained in the Services, the time has certainly come for putting an end to the miserable uncertainties of their position. Very many have proved themselves good friends in war and peace, and will have no difficulty in providing the General Medical Council with evidence of "satisfactory service." The claims of recent entrants who have made no contribution to the Allied war effort are of course more open to question; but in general we welcome a measure which if anything is overdue.

EARLY DETECTION OF POLIOMYELITIS

THE United States, with its heavier incidence of the disease, offers scope for observation of poliomyelitis that have not been paralleled in this country. In an analysis of 1125 cases treated in Minneapolis during the 1946 epidemic, Dr. John F. Pohl[1] suggests that the diagnosis can usually be established within twenty-four hours of onset. Headache, he says, was the most distinctive initial complaint, and this was usually of a severe, generalised, unrelenting type rare in the illnesses of childhood; it was particularly prominent during the first twenty-four hours in 57% of all patients. Fever was recorded within the first twenty-four hours in 80%, but this was in no way distinctive; the elevation of temperature was usually moderate. Otherwise the principal symptoms, in order of frequency during the first twenty-four hours, were nausea, vomiting, anorexia, stiff neck, stiff back, painful extremities, and general malaise with listlessness. Among the 4% of patients who complained of head cold or respiratory infection at the onset, the complaint was not generally confirmed on physical examination; and the 10% in whom sore throat was an early symptom were observed to have no inflammation of the throat. This symptom was ten times commoner in cases where bulbar symptoms ultimately developed than in those which eventually showed paralysis of spinal origin. In 22% of the patients there was a history of the symptoms having abated for 2–3 days after an initial and characteristic illness of about twenty-four hours.

The diagnosis, Pohl asserts, can be established very surely by physical examination. The patient lies quietly in bed and does not wish to be disturbed; he is irritable and resentful of interference. Spasm is indicated by the painful irritability of the peripheral tissues, and by the stiff neck, stiff back, or shortened hamstrings. Muscles elsewhere may be spastic; and spasm of the abdominal muscles may simulate that found in acute appendicitis. Spasm is found more often, and is more severe, in the paralytic than in the non-paralytic cases. Weakness or paralysis developed within the first twenty-four hours in only 5% of all cases. The cerebrospinal fluid (C.S.F.) is typically crystal-clear, is at a normal or low pressure, and has a moderately elevated cell count, n exceeding 350 per c.mm.; and in Pohl's series all cases and 1% of those in which paralysis had a normal C.S.F. cell count.

The diseases often confused with poliomyelitis, suggests, are the Guillain-Barré syndrome, enc meningitis, and transverse myelitis. In the Barré syndrome (or radiculoneuritis) the neck is not and weakness or paralysis tends to progress over the protein content of the C.S.F. is increased but the count is usually normal. The patient with men encephalitis is restless and hyperactive at the while transverse myelitis is marked not only by w but by sensory changes, which are most unu poliomyelitis.

CHILDREN IN DAY-NURSERIES

THAT the happiness and general well-being of c in a day-nursery depends on the quality of the s charge can hardly be questioned. But there are to young children living in a group which even t of care cannot wholly defeat. These may be c physical dangers from infection and emotional arising from the inevitable lack of individual love, and attention for a great part of the day. Yet nurseries are needed not only for the relief of mothers, but also—just at present—because must be released to work in industry. We must t try to assess accurately how serious these dan, how far they can be offset by benefits to the child, what age-groups suffer most.

The Medical Women's Federation, who have reviewed[1] recent studies in the field, quote the of Dr. Margaret McLaughlin that respiratory i was 2–8 times as common among 557 day-n children than among 641 children living at home, the higher incidence was present at all ages, and the nursery children developed respiratory inf at an earlier age. The older children in the n weighed more, but those under 2 years of age less, their counterparts living at home. Measles was times commoner among presumed susceptibles in nursery group than in the home group, and the was found particularly among children under 18 m these formed 33·6% of the nursery group against of those living at home.

The federation think that day-nurseries are principally to alleviate the effects of bad housing, crowding, and other social evils which prevent children from having a healthy and happy life at But group care is in any case not a sound health m they hold, for children under the age of 2 or 3. Every mother should be enabled to bring up her c in the home circle in the early years, and day-nu they suggest, should be regarded mainly as an in measure until the social disorders which stand in the of such home upbringing have been corrected. no doubt the ideal, but meanwhile it is encouraging note that day-nurseries do not always spell disaster the child, even from the dangers of infection. Dr. B Nisbet (p. 253) gives figures to show that in two nurseries at Kilmarnock infections did not seem to excessive, weight-gains were normal, and children had been to the nurseries seemed later, to their m mistresses, to be more self-reliant and better beha than children who had not.

While most doctors would agree that the child 2 is unfitted, both physically and emotionally, for life with other children, it is also certain, as Ma McMillan showed, that those between 2 and 5 greatly from community life; and though day-nu have not in the main achieved the standards of the nursery school, they have already travelled far from passive notion of the nursery as a place where a child be " minded " while his mother is elsewhere. If the gers to health can be overcome, or offset by benefits ich the child would lack at home, the day-nurseries ve in them the makings of good nursery schools, and ght be developed along such lines. As long as the al of uncrowded family life in good home surroundings nains far beyond the child's prospects and the country's se, nurseries still have work to do, and should be ouraged to do it at a better level.

HUMAN-MILK BANKS

LTHOUGH the wet-nurse of our grandmother's time almost disappeared, the virtues of human milk for feeding of infants in general and premature babies particular continue to be extolled. But practice, as al, lags behind precept, so that today less than half our babies are breast-fed for periods of 3–6 months, ile many premature and difficult-feeding infants are ied the benefits, if such they be, of human milk ause there is no large-scale arrangement for the ection and distribution of this commodity. Milk-eaux, as they are called, have been established in a nber of American cities and take one of two forms: ier the milk is expressed by the nursing mother in her house and is collected daily to be pooled and cessed at the milk bureaux, or the women attend at milk centre and express their milk manually under trolled hygienic conditions.[1 2] The collection of surplus k has of course long been practised in many maternity artments for the use of premature infants, and a centres, such as Queen Charlotte's, have collected k for distribution to a wider public. There is some son to believe that if there were larger supplies the nand would correspondingly increase. If this is so, collection of human milk must be so organised that final product is safe and palatable.

he necessary steps in the organisation of the human-k bank, either for hospital use or for wider distribution, the hygienic collection of the milk, and its sterilisation l preservation. In papers published on July 26 and our present issue Dr. Joyce Wright, with the coöpera-n of Sister E. M. C. Edwards, has shown how this can accomplished satisfactorily and inexpensively in a ternity department—even in one exposed to air ack. The collection of milk from mothers in a ternity unit has the advantage that the donors are ady in situ, but the disadvantage that small amounts milk have to be obtained from a large number of nors: where the mothers attend as outpatients, or ply milk from home during the whole period of tation, daily amounts of 10–20 ounces can be obtained m each donor and tuition in the cleanly collection of k is limited to the few. That instruction in milk llection so as to avoid gross bacterial pollution is ential, was demonstrated by Dr. Wright's finding of h bacterial counts in milk collected by the methods nmonly used in a number of maternity departments. e main sources of pollution were the unboiled collecting-ls, breast-pumps, mothers' hands, and nipples. The ption of simple measures to obviate these and other sible sources of bacterial contamination reduced the terial counts in the milk from a mean of over 2,000,000 ml. to 8600. Besides environmental contamination wever, the milk itself may be infected, particularly h *Staphylococcus aureus*, which in the experience of ferent workers may be present in appreciable numbers the breast-milk of more than half the women in a ternity unit. That this organism can be imbibed h impunity is attested by the numbers of babies who fer no upset from ingesting large numbers of staphylococci; but if enterotoxin-producing strains are allowed to multiply in milk after it is withdrawn the risk of serious gastro-enteritis among susceptible babies is obvious.

Milk should therefore be boiled and sterilised as soon as possible after it is withdrawn. Pasteurisation by the holder or flash method will destroy all vegetative bacteria, but this method of sterilisation is not easily carried out in a hospital ward without additional equipment. Wright and Edwards therefore recommend bringing the milk to the boil in a lidded saucepan, which practically sterilises the milk without affecting its palatability.

The last stage is preservation of surplus milk for use in the hospital when supplies are short, or for distribution outside. American workers have found that a relatively slow freeze method using a commercial ice-cream freezing-cabinet will serve the purpose admirably. The milk after sterilisation is distributed in 4–8 oz. amounts and frozen at −12°C, at which temperature it will keep without obvious deterioration in flavour for periods up to 8–12 weeks. Milk so preserved may be sent by rail packed in ice to considerable distances. If human-milk banks utilising lactating mothers outside the hospital are to be established, there are obvious advantages from the viewpoint of hygienic collection and preservation in having the donors attend as daily outpatients; but obviously they need an incentive, and the American practice of paying 5–15 cents per ounce of milk could be adopted. Sums of $1000–1500 have been paid out to donors for a session's attendance, and stories of mothers who save enough to put their children through college are told at these milk bureaux. An efficient and enthusiastic organiser is also needed to maintain a constant supply of donors if milk-banks are to continue their work satisfactorily. The experience and machinery that have gone to the organisation of blood-banks throughout the country could probably be made available if the pædiatricians are agreed that human-milk banks are as essential as the blood-banks have proved to be.

HUMAN RELATIONS

DIRECT study of community problems by the methods of the psychologist proved useful during the war, and is nowadays being applied to problems of industry. The Tavistock Institute of Human Relations, formed about a year ago by the Tavistock Clinic, and granted £22,000 by the Rockefeller Foundation, has a team of two psychiatrists, an educational psychologist, and an economist with psychological experience who study human relations in industry. They have already investigated situations in several factories, one of which was mentioned in the *Manchester Guardian* of June 25. A Yorkshire factory had difficulty in attracting and retaining staff. After talking with some of the girls employed, a member of the team was able to list 68 complaints and suggestions. Some of these related to the domestic economy of the factory, but more to the feeling the girls had that their work was unrelated to life and that they were regarded as parts of the machinery rather than as responsible humans. Not one of the complaints related to wages. The team have been able to offer constructive suggestions on this and other occasions.

This type of work is specially important today when the old distinction between employer and employed is disappearing in favour of a new spirit—a spirit in which both are partners in a joint enterprise. The first number of a journal designed to integrate the work of social scientists, on both sides of the Atlantic and in countries abroad, has just been published, and promises well. *Human Relations* is a quarterly sponsored jointly by the Tavistock Institute of Human Relations and the Research Center for Group Dynamics, Cambridge, Mass. The editorial committee (managing editor, Dr. Thomas Fairley) is composed of five representatives from each

Smith, C. A. *J. Pediat.* 1942, 20, 616.

Recommended Standards for the Operation of Mothers' Milk Bureaus, *Ibid*, 1943 23, 112.

of these bodies, most of the British members being doctors. There are also British and North American advisory editorial boards, composed of experienced British, American, and Canadian social scientists. These will collaborate to develop the journal, the purpose of which is to review original work done in any country, and to report research and contributions to theory and method. Social theory, it is hoped, may thus be related to social practice, and principles will doubtless emerge which will apply to the whole field of social science.

The well-produced first issue carries a paper on frontiers in group dynamics by the late Prof. Kurt Lewin. Other articles deal with a follow-up study of the civil resettlement of British prisoners-of-war, autistic hostility and social reality, residential management as treatment for difficult children, antisemitic prejudice in an American town, and task perception and interpersonal relations in industrial training. Future issues will carry in addition surveys of new techniques in social science and of legislative and administrative problems, as well as reviews of books and notes on current research.

DISEASE AND THE WEATHER

MAN, we are told, has inherited from his ancestors the predilection for a climate with a temperature of 47°F in March and of 62°F in June[1]; but in colonising the globe he has had to adapt himself as best he may to much less favourable conditions. The adversity is plainest in the tropics; here growth is slower, and, according to Mills,[2] the menarche, contrary to popular belief, occurs later than in temperate zones. Gelineo[3] has proved experimentally that the lower the temperature to which an animal has been accustomed the greater its response, by increased heat-output, to chilling; since heat-production and energy are interdependent, general vigour is presumably at its lowest in hot climates, and the risk of succumbing to infections is usually greater than in cooler zones. Invigorating climates have their special hazards, too: these include such disorders as diabetes, pernicious anæmia, exophthalmic goitre, leukæmia, Addison's disease, cardiovascular lesions, rheumatoid arthritis, and chronic respiratory infections.

It is generally agreed that the incidence of respiratory infections varies inversely with the atmospheric temperature, though the particular climatic factor involved is uncertain. How did it happen that, as Sir Andrew Davidson pointed out,[4] the incidence of children's diseases in Scotland, previously rising, fell sharply with the start of last winter's long cold spell? Perhaps real winter-sports weather, which tempts the young and active to disport themselves in the open air, has the opposite effect to the damp chilliness which drives everyone indoors. Experimentally[5] chilling, though not affecting resistance to the intraperitoneal injection of pneumococci, greatly increases the incidence of pneumonia after the intranasal inoculation of mixtures of pneumococci and mucin. Herrington and Moriyama,[6] in a statistical analysis of respiratory infections against climatic and socio-economic conditions, found a high pneumonia mortality in cold stable climates with (for lobar pneumonia) high precipitation; but, like other workers, they found no correlation of respiratory diseases with relative humidity. They concluded that the importance of climatic factors was far outweighed by that of the socio-economic ones, particularly urbanisation. This links with the observation of Haythorn and Meller,[7] that the smokiest wards of Pittsburgh have the highest pneumonia death-rates, and that deaths from pneumonia increase after periods of "smog" (smoke and fog).

Of even greater economic concern is the relation climate to the common cold. Several years ago a controlled experiment in America established that residence in a constant warm "climate" almost complet protected volunteers against infection. The mortality figures of the Social Survey ought to tell us in time exactly what weather it is that precipitates the annual outbreak of coughs and sneezes.

EXCERPTA MEDICA

As the achievements of scientific medicine go forward the great snowball of published work rolls behind them, and the busy doctor gazes with despair at its colossal proportions. Nobody can keep abreast of all that goes on: British readers are irritated by the lack of references to European work in publications from the New World, Americans no doubt shake their heads at the dar of Europe where American advances are not st as they should be. H. G. Wells in one of his books recommended an international bureau where scientific work should be gathered, sorted, collated, and then become accessible to all. Holland is attempting to this ideal by establishing an abstracting service of medical work published throughout the world. *Excerpta Medica* will provide "pertinent and reliable abstracts in English of every article appearing in every available medical publication in the world." The abstracts are being issued in the form of fifteen sectional journals of which will be published monthly.

The fifteen journals cover: anatomy, anthropology, embryology and histology; physiology, biochemistry and pharmacology; endocrinology; public health and social and industrial medicine; general pathology, pathological anatomy and bacteriology; internal medicine, tropical medicine and hygiene; pædiatrics; neurology and psychiatry; surgery and anæsthesia; obstetrics and gynæcology; oto-rhino-laryngology; ophthalmology; dermatology and venereology, radiology; and tuberculosis.

The central administration is at Amsterdam under the direction of a chief editorial board of three members, Dr. M. W. Woerdeman, professor of anatomy and embryology, Dr. A. P. H. A. de Kleijn, professor of rhino-laryngology, and Dr. W. P. C. Zeeman, professor of ophthalmology. Each section is placed under the direction of a separate board of editors, people of distinction and of many nationalities.

For example, the internal medicine section has 23 authorities on the editorial board, while the section on neurology has 34 residing in such varied places as Philadelphia, Stockholm, Chicago, Strasbourg, Berchem-Antwerp, New York, Amsterdam, Indianapolis, Oxford, London, Lund, Op Washington, Bristol, Prague, Cape Town, Copenhagen, Paris, Toronto, Warsaw, Zürich, Lisbon, Oslo, Utrecht, Barcelona, and Batavia. Great Britain is well represented in all but three of the sections.

The organisation stretches as far afield as China and through the courtesy of the embassy of the U.S.S.R. in the Hague it has been possible to make arrangements with Russian scientific organisations ensuring the hitherto inaccessible work will be abstracted. venture should do more than fill the gap left by journals as the *Zentralblatter* and *Berichte*, which doing the same sort of thing, but less comprehensively before the war. The difficulties of collecting, month, several thousands of abstracts, all needing careful editing, and many requiring translation into English are not small, but the first two sections to issue maiden numbers—*Dermatology and Venereology*, *Radiology*—show that a high standard has been set. it seems likely that the *Excerpta Medica* will prove important agent for disseminating knowledge of medi

CHILDREN IN DAY-NURSERIES

BRYCE R. NISBET
M.D.Edin., F.R.C.P.E., D.P.H.
MEDICAL OFFICER OF HEALTH, KILMARNOCK

WHEN Menzies [1] described her experiences with children two day-nurseries at Leyton she concluded, inter alia, t a substantial proportion of children under 2 years did not make satisfactory progress as judged by their ght gains over three-monthly periods. I have extracted nparable figures for the children in the two nurseries he Burgh of Kilmarnock. In this burgh one nursery, ned in April, 1943, has 40 places (temporarily increased 45 while the other nursery was being completed), l the other, a mixed nursery, opened in June, 1945, 43 places for day children and 10 residential billets. n three and a half years in nursery A 148 children e been admitted and have left; of these, 28 (18·9%) yed until they went to school. In one and a half rs in nursery B 46 children have been admitted and e left; of these, 12 (26%) stayed until they went to ool. Thus, in both nurseries 20·6% of the children nained until they went to school. Of these 194 ldren 7 left within a week, 14 others within a month, others in less than six months, and the remaining stayed more than six months.

The accompanying table sets forth the gains in weight the various classes of children. The numbers in each ss are small, but the findings are given for what they worth.

INFECTION

At nursery A, of 54 children admitted under the age 2 years who remained longer than three months, 7 veloped an infectious disease. At nursery B, of 36 ldren admitted under the age of 2 years who remained ger than three months, 17 developed an infection. At rsery A measles was the main trouble, and at nursery measles and chickenpox. At both nurseries the mber of children admitted under the age of 2 years o remained for a year or more was 38. During the t year of their stay in nursery A, of 20 children 5 aped an infection. At nursery B the number was and 7 escaped infection. Altogether, then, 12 out 38 escaped infection.

DISCUSSION

In connexion with the rapid turnover of children in rseries noted by Menzies, the figures for Kilmarnock not nearly so striking as those from Leyton, where 3 children were admitted and left and only 60 (16%) yed until they went to school. The comparable ures for Kilmarnock are 194 children admitted and t, 40 (20%) of whom stayed until they went to school. nost a quarter of the children at Leyton who left did within a week, whereas here a child leaving within a ek is an exception—3–4% of admissions. At Leyton ore than a fifth of the others left within a month, ereas at Kilmarnock only about another 7% did so. retting" as a cause for the withdrawal of a child s seldom put forward by a mother—in effect only ice.

It has been the rule here to note carefully the reasons, far as they have been ascertainable, for the child ving, and we find that by far the greatest number of ldren left the nursery because the mother gave up rk. We had often to request the mother to remove r child, as our policy was to admit only the children mothers working. The number of children removed cause the mother either gave up work or was told to do so was 99. When mothers were questioned, their reasons for giving up work fell into three main categories:

(1) The mothers said they did not like the work (57 cases).

(2) The mothers felt unable to continue work (15 cases).

(3) The mothers became pregnant again (12 cases).

A few children were taken into the nursery to allow mothers to try to get work; if the mothers failed, these children had to be sent out again. One or two women gave as their reasons for giving up work the fact that their husbands had been demobilised.

Further, 23 children were taken away because the mother was leaving the district. In 13 cases no reason was given.

Though the numbers of children in each group shown in the table are small, the weights seem to show that the gains, though not spectacular, are within the limits of normality and considerably better than the figures for Leyton.

As regards infection, it is difficult to get comparable figures for children in this district, since much depends on what infections are prevalent, and the position varied greatly from time to time. The figures extracted did not seem to show an excessive number of infections. Our experience is that at times there is a fairly heavy incidence, and then for long periods the incidence is slight.

GAINS IN WEIGHT

Age on admission (months)	Nursery	Total admissions	In 3 months		3–6 months		0–12 months	
			No. of children	Av. gain (lb.)	No. of children	Av. gain (lb.)	No. of children	Av. gain (lb.)
Under 12	A	33	22	2·4	16	2·3	8	8·6
	B	21	17	2·1	13	2·3	10	7·8
12–17	A	24	20	1·8	15	1·7	9	6·8
	B	12	9	1·2	5	1·6	4	5·8
18–23	A	17	12	1·6	6	2·3	3	7·1
	B	12	10	1·8	8	1·2	4	4·0
24–35	A	39	26	1·6	12	1·4	7	5·0
	B	20	10	2·2	6	2·2	4	7·8
36 and over	A	73	52	1·4	34	1·2	14	3·8
	B	28	18	1·0	16	1·2	4	5·0

The above admissions include not only the children who had left but also those who still remained in the nurseries.

An effort has been made to trace 40 children who have passed on to school. So far, detailed reports of head-mistresses on 27 children who have been long enough at school to warrant a report have been received. The general opinion is that the children who have been at nurseries mix well, are more self-reliant, and are better behaved than children who have not.

The general impression of the work in nurseries at Kilmarnock has been that they have fulfilled a need, and that the children have done well in them. There is a waiting-list for admission which has remained steady for the past few months at about 60 children, and there is no sign of the numbers diminishing.

SUMMARY

Of 194 children admitted to day-nurseries in Kilmarnock, 7 left within a week, 14 others within a month, 95 others in less than six months, and 78 stayed longer than six months.

The gains in weight were normal.

The number of infections in the nurseries seemed to be not unduly high.

The children who passed on to school mostly made a good impression on their teachers.

MISSILE WOUNDS OF THE HEAD

REVIEW OF WAR EXPERIENCE

THE *British Journal of Surgery*, which published a special supplement on penicillin during the war, is now producing a series of supplements on war surgery as a record of the achievements of British surgeons during the second world war. The first of these supplements is on missile wounds of the head.

G. JEFFERSON writes a characteristic and valuable account of infection of head wounds in the first world war and attributes the greatly improved results in the second world war mainly to antibiotics.

H. CAIRNS describes the arrangements for neurosurgery in the British Army—a base hospital in Oxford which treated some 13,000 patients during the war, and 6 mobile neurosurgical units overseas which together treated over 20,000 patients. This arrangement, which was economical with medical personnel, was coördinated with neurosurgery in the Canadian Army and the E.M.S. Cairns traces the evolution of surgical methods during the war—increasing thoroughness of debridement, primary closure of the wound with methods borrowed from the plastic surgeons, and the use of penicillin and sulphonamides. In a large series of brain wounds the incidence of fatal infection was reduced below 5%. The success of neurosurgery in the British Army is attributed among other things to careful planning before the outbreak of war, securing important items of equipment before the country's supplies and industry became so largely devoted to destructive weapons, the encouragement by the R.A.M.C. of high professional standards, and early segregation of the wounded, usually by air evacuation. He considers that the neurosurgical experiences of war strongly favour fusion of the medical services of the fighting Services. "In any medical service of the future, military or for that matter civil, services for evacuation of sick and wounded must inevitably include an air arm."

The operative methods employed are illustrated by a series of coloured photographs taken by Mr. HENNELL at Naples during the battle of Cassino; the photographs have been selected and described by J. SCHORSTEIN who performed the operations. The treatment of head wounds in the forward area is described by SMALL, TURNER, and WATT (North-west Europe, 1944–45), GILLINGHAM (Northern Italy), and R. T. JOHNSON (Burma), while the work of the Royal Navy is described by LAMBERT ROGERS, and that of an E.M.S. centre near Newcastle-upon-Tyne by ROWBOTHAM and WHALLEY. These papers with those previously published by Ascroft[1] (Middle East), Eden[2] (Western Desert and Tripolitania), Johnson and Dick[3] (Eastern Bengal), and others provide us with a fairly complete record of the development of a remarkably efficient neurosurgical service.

Special types of head wound receive special consideration. Wounds involving the paranasal sinuses are described by STEWART and BOTTERELL, of the Canadian Neurological Hospital, by CALVERT, and by JOHNSON and DUTT. The authors agree that most of these wounds require repair of the overlying dura to ensure against meningitis, cerebral aerocele, or brain abscess. It is remarkable to what extent the elaborate operations necessary for dural repair could be carried out during the rush of battle-casualties. There are differences of opinion as to what is the best method of operative approach, and this should probably differ from one type of paranasal-sinus wound to the next. An admirable description of the mechanism of fractures and of the means of detecting inconspicuous ethmoidal fractures by means of stereoscopic radiography of the orbit is given by JOHNSON and DUTT.

SCHORSTEIN describes 83 cases of intracranial hæmatoma, and shows the importance of the small penetrating missile of high velocity as a cause of intracerebral clot.

CONNOLLY recounts his experience of old untreated suppurating brain wounds in 113 Yugoslav partisans, among whom with the help of sulphadiazine and local penicillin there were 90 survivors, notwithstanding the fact that the majority of these patients had brain abscess, or brain fungus, or meningitis, on admission to hospital in Italy.

P. B. ASCROFT gives a most interesting survey of the cause of death in over 500 head wounds, in which he shows the importance of associated wounds in other parts of the body and the need in such cases of paying close attention to the general condition of the patient. Among those with head wounds alone, neural damage (41%), intracranial sepsis (40%), and intracranial hæmatoma (6%) accounted for the majority of deaths.

A special complication of wounds of the body of the lateral ventricle is described by CAIRNS, DANIEL, JOHNSON, and NORTHCROFT. In the course of healing the walls of the ventricle may adhere, with the result that the temporal horn of the ventricle is sealed off from the foramen of Monro, and localised hydrocephalus develops, often causing symptoms suggesting brain abscess. The condition is easy to recognise once one is familiar with it; and it is easily cured by excision of the choroid plexus of the temporal horn.

Bacteriological studies of infected head wounds were made in Oxford (CAIRNS, CALVERT, DANIEL, and NORTHCROFT), in the Middle East (ASCROFT and PULVERTAFT), and in Burma (JOHNSON) where a particularly virulent form of ventriculitis and meningitis due to *Escherichia coli* was encountered. In the Middle East (1942) staphylococcus preponderated. In Oxford, brain wounds from north-west Europe in 1944 showed a 14% incidence of major infections, in which clostridia, non-β hæmolytic streptococci, staphylococci, and coliform organisms were the common organisms, in approximately equal proportions. It is remarkable that in 354 brain wounds CAIRNS and others found not a single case of β-hæmolytic streptococcus infection; they attribute this to the use of penicillin and the fact that opportunities for cross-infection of wounds were reduced to a minimum by complete closure of practically all wounds at the primary operation. Clostridial infection did not produce spreading gas-gangrene of the brain or symptoms of generalised toxæmia; it was not particularly virulent, the intensity of the intracranial infection being proportional to the severity of the cortical wound rather than to the presence of clostridia. With modern chemotherapy the most virulent organisms in acute infections after brain wounds were non-β hæmolytic streptococci—organisms which are often relatively resistant to penicillin.

It is too early yet to assess the late results of these brain wounds, but RITCHIE RUSSELL reports the results in 200 cases 14–18 months after wounding. This follow-up shows that 145 of the 200 were working and that only 16% had had generalised convulsions after leaving hospitals. These preliminary results are encouraging; they may be attributed to the low incidence of wound infection and to the excellent methods of rehabilitation, which are briefly described at the end of the fasciculus.

Some unusual cases of brain wound are described at length, and there is a bibliography of literature on gunshot wounds of the head published in Britain between 1939 and 1947.

NEUROSIS IN FACTORIES

A SURVEY, made between 1942 and 1944, of the incidence of neurosis among factory workers, its effects on production, and of the predisposing factors, has now appeared.[1] It was undertaken by a team provided by the Industrial Health Research Board of the Medical Research Council under the direction of Dr. Russell Fraser; his collaborators were Dr. Elizabeth Bunbury, Dr. Barbara Daniell, Miss M. Elizabeth Barling, Miss F. Estelle Waldron, Miss P. Mary Kemp, and Miss Imogen Lee.

Diagnosis was based on clinical appraisal of any recent illnesses; each person questioned was submitted to special investigations, and where necessary to full physical examination; and was, besides, intelligence-tested, interviewed by a social worker, and assessed psychiatrically by one of the three physicians in the team. Over 3000 workers were studied ıg 80% of a random sample from a total of 30,000 employed 3 light or medium engineering factories.

[2] Eden, K. *Ibid*, p. 689.

[3] Johnson, R. T., Dick, R. C. S. *Ibid*, 1945, ii, 193.

[1] The Incidence of Neurosis among Factory Workers. Medical Research Council: Industrial Health Research Board. Report no. 90. London: H.M. Stationery Office. Pp. 66. 1s 3d.

FINDINGS

he term "neurosis" was defined as including only se disorders which were clearly illnesses both in the tor's and the patient's opinion, and which were h neurotic in nature and also disabling—they had rly always caused absence from work. In practice, re were anxiety states, mild depressive states, essional states, hysteria, and a few instances of chosis. The term was not used to cover organic ous disease or mental defect. "Minor neurosis" used to cover such things as psychosomatic illness, raine, functional dysmenorrhœa, peptic ulcer, and r-like dyspepsia, as well as abnormalities of person- y sufficiently marked to indicate reduced mental health. n the sample of over 3000 men and women 10% % of the men and 13·0% of the women) had suffered n definite disabling neurotic illness; and a further % (19·2% of the men and 23·0% of the women) from or neurosis during the course of 6 months. Neurotic ess caused $^{1}/_{4}$–$^{1}/_{3}$ of all absence from work due to illness, $^{1}/_{8}$–$^{1}/_{4}$ of all absence from whatever cause. It accounted the loss of 1·09% of the men's possible working days 2·4% of the women's—a loss equal to 3 days' absence rly of every man and 6 days' yearly of every woman died. Neurosis was as common among those in the re skilled as among those in the less skilled jobs: ure to employ those with neurotic illness would thus uce the country's reservoir of skilled labour.

ince people differ in their susceptibility to illness, attempt was made to study their constitutional pre- position at the time of the survey. This was done by iewing the past health record, age, physique, per- ality, employment record, and intelligence level of h worker studied.

hose who had suffered materially from illness before the r were found to suffer similar illness during the six months died. Age was found to have little relation to recent illness; men of 41–60 experienced slightly more physical illness n the younger men. Physique, in the sense of strength l solidity of build, was related to recent experience of ess, those with better physique having less physical and rotic illness and less absence from work than the rest ng the 6 months of the survey. Those of adaptable and ble personality, persistent in the face of difficulty, had a er incidence of neurosis than the rest, while those whose its had become fixed suffered more than the average from ent neurosis. Those with a history of repeated changes of rk, or of more than 6 months' continuous unemployment ore the war, had had more recent physical illness, and bably more neurotic illness too, than others. People of intelligence suffered more physical illness than the rest, sumably because they were not so good at looking after mselves.

FAVOURABLE CIRCUMSTANCES

The team studied circumstances associated with less n the usual incidence of neurosis. First of these, narkably enough, was *more* than average normal mestic responsibilities, coupled with less than 75 hours ekly of industrial duty.

Examples of "average" normal domestic and allied ponsibilities, as judged by the team, are those borne by male householder with a family of 1–3 children of school and under; by a housewife with no children at home t doing her own housework as well as full-time work at the tory; and by a housewife with 1–3 children at home doing r own housework and also part-time factory work. Those th "more than average" responsibilities had similar duties those just given, but had, in addition, to shoulder any one the following: a family of more than 3 children under 14; rtially dependent parents; at least 12 hours' travelling to d from work weekly; (if a mother) sole financial responsi- ity for a child; other significant duties such as another rt-time job, civil defence work occupying more than 7 hours reek, or executive duties in some local organisation.

Other strong defences against neurosis were more than erage social contacts and congenial work. Mere free- m from worry seemed to be of little account beside ese, though a small group with considerable sources worry had more neurosis than the rest.

UNFAVOURABLE CIRCUMSTANCES

More than the usual incidence of neurosis was found among those doing more than 75 hours' work a week in the factory, those taking the least adequate diets, and those with restricted social contacts, recreation, or leisure interests. The incidence was also raised among widows, and among married women with only partial home duties. Those with considerable abnormal responsibilities—such as illness or death in the family, separation from close friends, and special shopping, housing, money, or transport difficulties—also showed a high incidence. Other factors favouring neurosis were boring or distasteful work; very light or sedentary work; work requiring skill inappropriate to the intelligence of the worker; assembly, bench, inspection, or toolroom work; work requiring constant attention, especially if it offered little scope for initiative or technical responsibility; work programmes with little variety; and badly lighted work.

The report notes that more variety and more scope for initiative and interest could be introduced without any fundamental alteration of production programmes. Poor lighting increases strain and makes the surroundings gloomy. Unsatisfactory human relationships inside the factory are also likely to influence emotional health, and therefore output.

PHYSICAL ILLNESS

More physical illness than the average was found among those having their first taste of factory work, those on very light or sedentary work, men doing the heaviest work, those receiving low wages, and those married women who had partial or minimal home duties.

Absence from work was below the average among those who liked their work, and above the average among married women with full or partial home duties, those with abnormal responsibilities, those working more than 75 hours a week, those receiving low wages, and those doing very light or sedentary work.

CONCLUSIONS

The team note that good welfare and social work within and without the factory would probably alleviate and prevent neurosis, as would better facilities for its treatment. Their main finding is that 10% of the workers studied suffered from disabling neurotic illness, and that neurosis caused over a quarter of all absence from work due to illness.

Medicine and the Law

Notifying the Coroner

Dr. Robert Forbes recalled in a recent letter (July 26, p. 153) the opinion of Sir Roland Burrows, K.C., obtained jointly by the Medical Defence Union and the Medical Protection Society, on the duty (if any) of surgeons and physicians to notify the coroner of the death of a patient. The first of the five points enunciated by learned counsel was that "there is no legally enforceable duty resting on a medical practitioner quâ medical practitioner to report any death to a coroner." The opinion was presumably confined to duties at common law; there is a limited and perhaps indirect obligation to notify under statute. Thus under the Habitual Drunkards Act, 1879, where anyone detained in a retreat dies, the principal medical attendant of the retreat must sign a statement of the cause of death, and a copy, certified by the licensee of the retreat, must be transmitted to the coroner. So also if the patient dies while absent from a retreat under licence, a duly qualified medical practitioner must sign a similar statement and the person in whose charge the patient had been placed must notify the death to the coroner, to the registrar of deaths, and to the local authority. It will be remembered too that a person in charge of an institution, hospital, or nursing-home, or of a single patient, must give the coroner notice of the death of a mental patient within the "prescribed time"—i.e., before the expiration of the second day after the death. That obligation was laid down in the Mental

Treatment Rules made under the Act of 1930, replacing section 319 of the Lunacy Act of 1890. Omission to discharge this duty is a misdemeanour. Two other statutory provisions with which the medical profession is not particularly concerned may be added. In the case of a foster-child or an adopted child the person having care of the child must give the coroner written notice within 24 hours of the death. The coroner must then hold an inquest unless, after receiving a certificate of the cause of death from the medical practitioner who has personally attended the child in its last illness, he decides that no inquest is necessary.

Such are some of the inroads which statutes make upon the common law. If these examples mildly qualify the general statement quoted above from counsel's opinion, they do not seriously diminish the importance or authority of the advice. On the other hand, as Dr. Keith Simpson says in our correspondence columns this week, "it is to be hoped that a too rigid interpretation of the Burrows opinion will not have the unfortunate effect of leading doctors to depart from the more practical custom of informing the coroner direct, either through his officer or the police."

Overdose of Carbachol

In our account (July 26, p. 148) of a fatality after an overdose of carbachol it was stated that the drug used was 'Moryl.' This is incorrect. Another preparation of carbachol, made by different manufacturers, was in this case the cause of death.

Public Health

AN OUTBREAK OF STAPHYLOCOCCAL FOOD-POISONING

J. MORRISON RITCHIE
M.A., M.B. Glasg., D.P.H.
BACTERIOLOGIST

D. L. MURRAY
M.B. Edin., D.P.H.
SENIOR ASSISTANT MEDICAL OFFICER

M. HOLGATE
M.R.San.I., M.S.I.A.
CHIEF SANITARY INSPECTOR

BIRKENHEAD

ON June 28 and 29, 1947, there was an outbreak of food-poisoning in Birkenhead and district, involving some 171 persons, 97 of whom received hospital treatment. The symptoms, which appeared $3\frac{1}{2}$–$4\frac{1}{2}$ hours after eating infected food, were vomiting, diarrhœa, and abdominal pain. All the patients recovered, the great majority in two or three hours, but a few were detained in hospital for two days.

The chief sanitary inspector was called out by the Birkenhead police at 9.40 P.M. on Saturday, June 28, and informed that patients with food-poisoning had been taken to hospital from all parts of Birkenhead. He got in touch with the acting medical officer of health and the borough bacteriologist, and a visit was made to a hospital where about 30 persons were being treated. They were guests from three wedding parties. Guests from a fourth wedding party were being treated at another hospital within the borough, and some children from a child's birthday party were detained at the county hospital.

Inquiries immediately revealed that catering for all the parties had been carried out either wholly or in part by one firm. The one food which had been supplied to all the parties was trifle, and such inquiries as could be made under the very difficult circumstances showed that all the persons affected had eaten trifle.

One of us (D. L. M.), who was acting as medical officer of health, contacted the manager of the catering firm and ascertained that the suspected food had been supplied only to special orders. Similar trifles were being served at a dance then in progress at the town hall, and the police confiscated all those not already eaten.

Bacteriological investigations were begun at once, and are referred to in detail below.

On Sunday morning, June 29, a meeting was held of the manager of the catering firm, the medical officer of health, and the chief sanitary inspector. The firm's order books were examined, and a list was obtained of 14 parties at which trifle had been supplied. The sanitary inspectors, working all day on Sunday, obtained complete lists of guests attending the various functions and visited all those living in Birkenhead. At functions where trifle was not served no cases of illness were reported. All the neighbouring local authorities coöperated in obtaining similar information from persons resident in their area. Out of 380 persons traced, most of whom had eaten trifle, the number affected was 171.

Samples of the ingredients of the trifles were submitted for chemical and bacteriological examination. Chemical analysis showed that all the materials were free from poisonous matter, but bacteriological examination produced very interesting results.

BACTERIOLOGICAL INVESTIGATION

The bacteriologist was notified by the chief sanitary inspector at 10.30 P.M. on Saturday, June 28. Outfits were collected, and a visit was made to a hospital to which some of the patients had been taken. Vomit and fæces had been plentiful but were by that time curiously scarce, most of the containers having been washed up for re-use. Only five vomits, and these mere residual fluids, together with three fæces were available for test. These were put on culture forthwith.

At midnight samples of all the foodstuffs involved, consisting of trifles, jellies, meat sandwiches, wedding cakes, and sausage rolls, together with whisky, wines, and lemon squash, were collected from the police. These were also cultured forthwith.

On Sunday, June 29, subcultures were made, and further vomits and fæces were received from another hospital.

By this time it had been established that trifles delivered from a certain bakehouse were the only common factor in all cases. *Staph. aureus* was isolated from several of these, and from a portion of jelly which had formed part of yet another batch of trifles from the same bakehouse. The drinks and all the other foods were clear, as were the ingredients of the trifles, examined separately. No evidences of salmonella infection were found anywhere, though many late lactose fermenters were found in the fæces examined. Biological tests were carried out with the trifle on guineapigs, by feeding experiments, with negative results.

On Monday, June 30, the bakery was visited, and the staff who had dealt with the trifles were examined. Swabs were taken from throat, nose, and ears of all concerned. An almost healed stye on the left eye of one (A.B.) was also swabbed. Cultures gave the following results:

A.B.	(throat)	*Staph. aureus* abundant
A.B.	(nose)	" " "
A.B.	(ears)	" " "
A.B.	(styo)	" " "
C.D.	(nose)	A few *Staph. aureus* (three colonies in all)

The others were all negative.

A.B. gave a history of having been off colour now and again for a considerable time, attributed to having given many pints of blood to the blood-bank. She had had a discharging ear some time previously, which apparently healed.

C.D. gave no history at all of any illness and, beyond being of a pale type, appeared perfectly healthy.

Coagulase tests were made of all the cultures available with the following results:

Trifle (all sources)	++
Jelly from trifle	++
C.D. (nose)	++
A.B. (throat)	+
A.B. (nose)	+
A.B. (ears)	+
A.B. (styo)	+
Vomit	+
Fæces	±

The other staphylococcus cultures gave no coagulase reaction, but the variation in the intensity of the positives gave the first hint of the real cause of the outbreak.

ultures were sent to Dr. V. D. Allison, of the Central blic Health Laboratory, Colindale, London, for typing phage reaction, with the following results :

Trifle	42 D
Jelly from trifle ..	42 D
C.D. (nose)	42 D
A.B. (throat)	52 A
A.B. (nose)	52 A
A.B. (ear)	52 A
A.B. (stye)	52 A
Vomit untypable	
Fæces untypable	

he source of the infection was therefore not the vily infected and clinically obvious A.B., but the er operative, C.D., who was apparently only lightly cted, and in the nose only. The staphylococci being lifferent types proves that there is no question of one rative having infected the other.

n interesting feature, which unfortunately could not proved, was that some of the guests at one of the ctions were reported to have had "boils and a stye" r the outbreak. News of this reached the laboratory a week or more after the occurrence. Though steps e taken to get in touch with all the groups of victims, further cases were noted, and those who had suffered cleared by the time the laboratory was notified, no staphylococci could be obtained. The report is ous, especially as there can be no question of post-hoc gestion, since it was mentioned before any suspicion *taph. aureus* had been made public. It is felt that point might be gone into in future outbreaks.

DISCUSSION

he origin and method of infection are clear. The ges for the trifles were broken up by hand about M. on Friday, June 27. The weather was extremely and steamy—ideal for the proliferation of *Staph. us* and the production of its toxin—and remained ntil the food was eaten next day. The trifles had efore about 24 hours' incubation. That certain parts the trifles were more heavily contaminated than ers (171 persons affected out of over 300 known to e consumed trifle) is a reasonable assumption from method of preparation, the sponge being a solid lium at the time of inoculation.

SUMMARY AND CONCLUSIONS

n outbreak of food-poisoning by *Staph. aureus* toxin due to the consumption of trifle.

he bacteriological evidence shows that infection took e from an operative in the bakehouse where the trifle prepared.

he weather was extremely hot and steamy for at least hours after preparation—right up to the time the l was eaten.

he advisability of adequate refrigerator accommoda- being available to all bakehouses where food has to ept overnight is indicated.

taph. aureus was found in two operatives, one heavily cted and clinically probable, the other slightly cted only and not clinically diagnosable.

he clinically probable operative was proved by ng to have no connexion with the outbreak, whereas lightly infected and otherwise apparently healthy ative was the source of contamination.

horough bacteriological investigation is therefore ortant even when the source seems obvious. The real in of infection was here effectively camouflaged cally, and could easily have been missed altogether less thorough bacteriological technique on the spot.

he danger of destruction of evidence by nurses in reaks of this character should be emphasised in curriculum. The material available in an outbreak his magnitude should have been much more volumi- than it was. Only juice, for example, was available the vomited material, with practically no food.

he problem of prevention of further outbreaks is more serious as the source of this infection was not cally apparent. The warm weather acting as an bator undoubtedly played a major part in the luction of the staphylococcal toxin. A laboratory ice might advantageously be given to places of food luction on the following lines :

) Only those engaged in preparing food which is not to ooked after preparation are concerned.

(*b*) Distributors of finished foodstuffs are not at present being considered. The essential feature in this outbreak is felt to be the long incubation within the material after preparation. Distributors, even if carriers, can under any reasonable conditions infect only portions of the surface and are therefore in a different category as potential sources of infection.

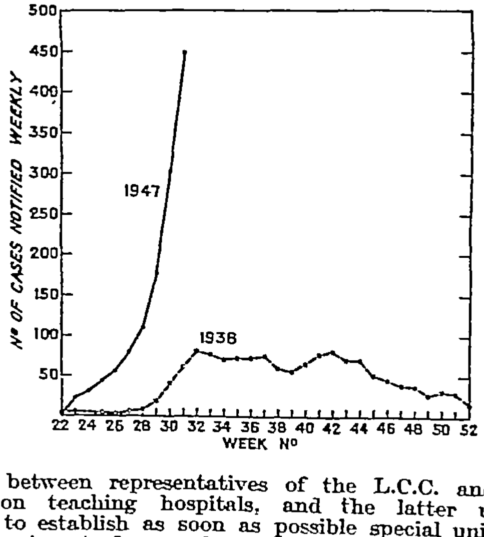
(*c*) As *Staph. aureus* can be clinically unsuspected, the services of the local public health laboratory should be available, so that operatives included under paragraph (*a*) can, during hot weather, be examined as a routine for *Staph. aureus* at such intervals as are practicable, probably monthly. Acute septic conditions, however small, should be reported to managers, who can then send the patient at once for examination. Simple plating is all that is needed ; but, if *Staph. aureus* is found, it can then be typed. No-one need be suspended from duty unless the organism is present. As refrigerators become more generally available, the tendency towards *Staph. aureus* outbreaks may well diminish.

We wish to thank Dr. Allison for typing the strains of staphylococcus isolated ; and Dr. F. G. Foster, medical officer of health, for permission to publish this report.

Poliomyelitis

During the week ended Aug. 2, 448 cases of poliomyelitis were notified in England and Wales. This is an increase of about 50% on the figure for the previous week (302). A rate of increase of this order has now been recorded for the last four weeks, and provisional figures available for the week ended Aug. 9 suggest that it is still continuing. The largest increases in notifications were in the following county areas, which include county boroughs (the figures for the previous week are shown in parentheses): Durham 45 (20) ; Lancs 36 (17) ; Yorks, East Riding, 16 (3) ; Yorks, West Riding, 70 (52) ; and Surrey 32 (15).

During the week ended Aug. 9, 106 cases were removed to hospital from the London County Council area as against 55 the previous week. Consultations have been held between representatives of the L.C.C. and the London teaching hospitals, and the latter undertook to establish as soon as possible special units for the treatment of cases of poliomyelitis in the acute stage occurring in the London area ; these additional beds will be allocated through the Emergency Bed Service (Tel. : Clerkenwell 6571).



PATHOLOGICAL SPECIMENS

As a result of a recent memorandum on acute poliomyelitis by medical officer to the Ministry of Health, which appeared in our issue of July 26, a large number of specimens have reached the Virus Reference Laboratory, Colindale Avenue, London, N.W.9. The laboratory are very grateful for the coöperation of clinicians and pathologists. It is, however, necessary to emphasise that the virus of poliomyelitis has never been isolated from cerebrospinal fluid and that specimens of C.S.F. were requested only from cases where it was possible that some other neurotropic virus might be the cause of the illness. Such specimens of C.S.F. must be packed in ice for transport. Specimens of fæces are not requested at present, since monkeys, which are the only animals suitable for primary isolation of the virus, are not available for this purpose.

In addition to the post-mortem specimens in glycerol saline for the Virus Reference Laboratory, it is also requested that representative specimens of spinal cord, as much as possible of the brain stem, and pieces of cortex, including the motor area, be preserved in formol saline and sent either to Prof. J. McIntosh, Middlesex Hospital, Mortimer Street, London, W.1, or to Dr. J. G. Greenfield, National Hospital for Nervous Diseases, Queen Square, W.C.1.

Beds for Poliomyelitis at Teaching Hospitals

The London teaching hospitals, some of which were already admitting occasional cases, have in the past week made special provision for the reception of acute cases of poliomyelitis. As is announced above, the distribution of cases is being arranged in conjunction with the Emergency Bed Service of King Edward's Hospital Fund for London. The allocations already made, some of which are only a first instalment, are as follows:

Hospital	*No. of beds* *Male*	*Female*	*Children's*
Charing Cross:			
Mount Vernon, Northwood	5	5	—
Guy's	4	4	3
King's College	3	3	4
London	12	12	10
Middlesex	8	6	16
Royal Free:			
Liverpool Road Annexe	6	—	6
Rheumatology unit, North-Western Hospital, Hampstead	4	4	—
St. Bartholomew's		Total of 42	
St. George's	9	9	—
Associated Victoria Hospital for Children, Tite Street	—	—	18
St. Mary's	2	2	2
St. Thomas's	22	—	—
University College		Total of 23	
Westminster	—	12	—

St. Thomas's and Westminster hospitals have a reciprocal arrangement for the transfer of female and male cases.

Some hospitals have established the beds in isolation units with separate medical and nursing staffs; while others, to conserve trained personnel, are admitting cases to the general wards, where they are nursed with "barrier" technique. The teaching hospitals undoubtedly have more nurses at their command than the London County Council institutions; and these dispositions will give welcome relief to the L.C.C. hospitals from a growing strain on their resources, already severely taxed by the continuing prevalence of measles, whooping-cough, and gastro-enteritis.

Diphtheria Prophylaxis

With the aim of getting at least 75% of babies immunised in their first year the Minister of Health is launching a further drive. In a brochure he suggests ways by which local authorities may contribute—through advertising in local newspapers, posters, films and slides, and leaflets; but "local publicity should have as its basis a scheme of personal persuasion."

Infectious Disease in England and Wales

WEEK ENDED AUG. 2

Notifications.—Smallpox, 0; scarlet fever, 803; whooping-cough, 1737; diphtheria, 200; paratyphoid, 19; typhoid, 6; measles (excluding rubella), 6954; pneumonia (primary or influenzal), 271; cerebrospinal fever, 48; poliomyelitis, 448; polioencephalitis, 39; encephalitis lethargica, 2; dysentery, 53; puerperal pyrexia, 145; ophthalmia neonatorum, 80. No case of cholera, plague, or typhus was notified during the week.

Deaths.—In 126 great towns there were no deaths from enteric fever or scarlet fever, 2 (0) from diphtheria, 1 (0) from measles, 8 (2) from whooping-cough, 52 (4) from diarrhœa and enteritis under two years, and 3 (0) from influenza. The figures in parentheses are those for London itself.

The number of stillbirths notified during the week was 252 (corresponding to a rate of 27 per thousand total births), including 32 in London.

In England Now

A Running Commentary by Peripatetic Correspondents

My asthma season begins every year during As Week and closes with the St. Leger. Once or twic has for some reason embraced the Cesarewitch, but it usually over by the time the Manchester Handicap has been run. In the meantime I suppose my poor old bronchi are being tormented by some devilish (and so far completely anonymous) pollen, emanating from an inoffens little plant I probably pass ten times a day without s much as a malicious glance. I know I'm too late for the buttercups, though, whose undramatic reproduct activity, given the right climatic conditions, fires of annual army of sneezers and wheezers. They tell me as soon as the fields are speckled yellow there has to be a rainy day followed by a fine morning, and the windows in Harley Street shoot up appreciati as they get ready for the rush.

My asthma has survived all sorts of times and con tions since my first attack was put down by my nur wandering about with wet feet in Skegness at the of four. It is bad in Cornwall, Cambridge, and Cotswolds, while the only spots that seem to do it good are, unfortunately, Paris, St. Moritz, and M Carlo. The colourful sun-drenched English countryside has for me only the dangerous beauty of Borgia. Nothing suits my respiratory tract so nicely a smoke-filled, stuffy, overcrowded, low-ceilinged as conveniently provided by the *innkeepers* England.

I started having treatment shortly after the ori Skegness incident. The family doctor, I suppose in good faith, packed me off to an E.N.T. surgeon who removed m tonsils and adenoids, with half my uvula as an ex They left me alone after that for no less than ten when I was operated upon again (for tonsils and adeno *Nowadays they content themselves with* X-raying sinuses, which remain, thanks be to God, frustra clear.

The next line of treatment I initiated at Reading an advertisement in the papers for some tablets guaranteed "to miraculously stop attacks in 30 seco I bought five bob's worth and swallowed a couple, m watch on the table in front of me. At the end of seconds *nothing* had happened, and I haven't tried the again since. Then I took to smoking herb cigarettes, whi gave me bronchitis and lots of fun when passed along row of friends in the darkness of the cinema. But a therapeutic measure and as a smoke they were eq unsatisfying.

With an increase in my medical knowledge came widening of my circle of treatment. As an undergrad at Cambridge I was skin-tested. A charming phys scratched a pair of tramlines down my left forearm great enthusiasm and no asepsis whatsoever. I found *hard to believe that such* delightfully named p should be the cause of all the trouble—Soft B Vernal and Cock's Foot for example, not to men Yorkshire Fog, Dog's Tail, and Sheep's Fescue. neither, apparently, were they. The only concl reaction was for lobsters and so forth, though I ha eaten *Homard à l'Americain* in midsummer with reprisal. I was *desensitised* against pollens, regardless effect on asthma—nil.

The next step was breathing exercises. These are doubt excellent, but I am one of those unfort people who can never follow *printed* directions for do anything, from blood-sugar estimations to (once upo time) dancing the tango. After getting myself into *sorts of respiratory contortions*, I let them slide.

About this time I qualified, mainly because they me up to a fellow-sufferer in the Conjoint clinical. the summer *sibili* set in again, I reached the sad concl there was but one therapeutic avenue down which had not yet taken refuge. I should have to se psychiatrist.

We had several little chats together, the psychia and I. Every visit convinced me more strongly neurotic I was, as he dug firmly into my past, care shaking the psychopathic worms out of each spad Had I ever any trouble with my sex life? Well, there time I inadvertently asked both staff nurses on my d to the same party on the same night. . . . How about ms? What sort of dreams did I have? I never m, except that someone is waking me up, when they My childhood then—was it unhappy? We even- y got back to Skegness at the age of four. He came ie conclusion my asthma was probably the result of dering about with wet feet.

now I have no alternative than, like Lord Beaver- k and King William III, to live with my asthma. n't worry about diet, but if I'm sharing a room with ne I warn them that the terrifying wheezes likely cur in the dead of night sound much more alarming they actually are. I take ephedrine (which keeps wake), 'Benadryl' (which sends me to sleep), and inophyllin' (diuretic). I've tried atropine, absti- e, alcohol, and adrenaline. Only the last is of any t all, but it's terrifying stuff to take. The injection s like a wasp, you can hear your heart-rate climbing igh, the bottom begins to drop out of your stomach, the top of your head wants to blow off. This is all worse by a concurrent feeling of panic. My rite weapon is an atomiser loaded with adrenaline 0. Carrying this in my pocket all summer spoils hape of my suits, but I'd rather leave my trousers me than be without it. By sneaking off into a quiet r for a sniff, à la Cocaine Joe, I can usually get lerful relief if I catch the attack early enough. I ecommend it, and often have done.

t long ago I saw two other beneficial measures ioned in the literature—boxing and marriage. But e adopting such heroic treatment, I'd like to try a nore cures first. Anyone know any?

* * *

vas interested in your peripat's difficulty in explain- he whereabouts of the Royal College of Physicians taxi-driver, as I had a somewhat similar experience. like my illustrious colleague (quarter of a century R.C.P.) I am an M.R.C.P. of one week's standing, although not in the taxi-rider's group I thought uld celebrate the admission to membership by this extravagance.

n inquiring my destination, the driver's face assumed ank stare. After a few moments' cogitation he enly smiled and said, "I know what you mean, the end of Canada 'Ouse."

* * *

e elderly French colonel from whom we have hired ummer chalet on Lake Geneva arrived this afternoon r back door dripping wet and clad in nothing but a of a cut so ancien régime that, fortunately, it reached knees. After kissing my wife's hand and exchanging sual prolonged compliments, he asked (*a*) if I was) if I had any chloroform, (*c*) if not, could I get ? My wife answered (*a*) that I was paid to sit at sk in the Palais des Nations from 8.30 A.M. to ; (*b*) that not, therefore, being a practising doctor, d no chloroform; and (*c*) that, being a foreigner, were doubtless regulations which would prevent etting any; and riposted by asking what he wanted ? It seemed that the old lady—also French—with n he was now lodging some 500 yards up the shore allen and cut her head, and, he greatly feared, broken rist.

wife at this point dragged him indoors—for the her was cool—and administered brandy, which he ved with many compliments on "ce vhisky déli- :" and a long story of how he had once had some Scottish regimental mess. He had come as quickly ssible for the chloroform in his boat, he explained, his elderly dog, wishing to accompany him and y falling into the water, he had fallen in himself ving her. But fortunately, Madame, I had pre- ly removed my coat, and (with a modest glance wards) it suffices. My wife then asked if the doctor sent him for the chloroform. But, no, it was not ssary to call in the doctor; only he feared that the lady would not sleep tonight without chloroform! r further compliments and hand-kissing, he took elf off, chloroformless but cheerful, leaving my dazed but clear at least on the causes of French pulation and why age is so respected in that try.

Letters to the Editor

INFORMING THE CORONER

SIR,—The opinion of Mr. (now Sir) Roland Burrows on reporting deaths to the coroner, which has once more been quoted in your columns, this time (July 26) in a letter from the secretary of the Medical Defence Union, however correct in law, is capable, if rigidly applied in practice, of bringing about one very unfortunate consequence.

While the doctor may have no "enforceable duty" to report to the coroner, very valuable time may be lost if he refrains from at once reporting a case that he *knows* will ultimately reach the coroner by way of the registrar of deaths. If, in such a case, he is content merely to drop his certificate in the post-box, two to four days may elapse before the pathologist can make his autopsy on the coroner's instructions. In hot weather this delay may be fatal to a useful autopsy owing to decomposition.

The remark attributed to Mr. Bentley Purchase on p. 147 of your issue of July 26 "that the coroner's desire to be promptly informed of cases in which an inquest may be necessary is based on the convenience of the relatives, not of the coroner himself" perhaps understates the urgency of the matter. It is no less important to the coroner that the pathologist whom he requests to perform an autopsy shall have the best facilities that can be offered: if the body has been allowed to decompose for two to four days the one really important "facility"—good fresh material for examination—will have been lost. Prompt autopsy is more important than prompt burial.

It is to be hoped that a too rigid interpretation of the Burrows opinion will not have the unfortunate effect of leading doctors to depart from the more practical custom of informing the coroner direct, either through his officer or the police.

Guy's Hospital, S.E.1. KEITH SIMPSON.

NUTRITION IN PREGNANCY

SIR,—It is generally accepted that the vital statistics of pregnancy and infancy are sensitive indices of the health of populations, and war-time experience in this country suggests that of all the environmental factors concerned, nutrition is probably the most important. The chief medical officer of the Ministry of Health[1] writes that "the national provision of milk and vitamin supplements . . . together with rationing and the greatly improved quality of the national loaf has contributed to the gradual decline in the maternal, neonatal and infant mortality and stillbirth rates" during the war. Baird[2] has pointed out that prematurity and stillbirth are more than twice as common among hospital as among nursing-home confinements, despite equivalence of medical care, and has given reasons for believing that nutrition is the most likely cause of the difference. Sutherland[3] has shown statistically that the stillbirth-rate is associated with nutrition and antenatal care, but not with overcrowding and its concomitant social handicaps.

In the light of such evidence some of Prof. C. A. Smith's findings[4] in an inquiry into events in north-west Holland during the winter famine of 1944–45 are unexpected. His facts were obtained from the records of a maternity hospital in Rotterdam and from other sources, several months after the famine ended. National statistics and data supplied to him by the Oxford Nutrition Survey indicated that during the early months of 1945 pregnant women in the affected Dutch cities were consuming less than 1000 calories daily, their diet having been reasonably adequate before the German blockade started in September, 1944, and again becoming fairly adequate soon after the liberation in May, 1945. That there was in fact severe undernutrition is supported by the statement that about 50% of women suffered from amenorrhœa, and that there was a fall in the birth-rate to about one-third of normal. The average birth-weight of

---

3. Sutherland, I. *Lancet*, 1946, ii, 953.
4. Smith, C. A. *J. Pediat.* 1947, 30, 229.

infants born in hospital fell to about 90% of normal, but the weight attained or exceeded normality within two months of the liberation, indicating that the effect was produced by underfeeding during the last part of pregnancy. Prematurity (defined as birth-weight of 5 lb. or less) was not significantly increased in "hunger" pregnancies. Stillbirths actually decreased, according to hospital, municipal, and national statistics; and there was no increase of neonatal mortality (defined as deaths in hospital during the first 10 days of life). The proportion of infants who were breast-fed, and the duration of breast-feeding did not show any significant abnormality.

Considering the amount of famine in the world recently, there are surprisingly few parallel accounts in the literature. Antonov [5] has described experience in the Leningrad State Pædiatric Institute during 1942, when amenorrhœa became "widely prevalent" among women; and the average birth-weight of infants at the height of the siege fell to about 85% of normal. The hospital stillbirth-rate doubled, and prematurity (defined as length at birth less than 47 cm.) became very common. There was a high neonatal mortality (21·2%; no definition of neonatal mortality is given). Capacity for breast-feeding was never abolished, but less milk was produced and the period of breast-feeding became shorter. Struthers,[6] whose writing reflects considerable scientific scepticism, says that in the large German cities in 1945, when starvation seemed imminent, there was no change in birth-weights, but prematurity and missed abortions were more common than usual, and breast milk tended to fail after about six weeks. Amenorrhœa was very common among women in the Ruhr; this he attributed to emotional factors. Middelhoven [7] reports that in Amsterdam during the famine many infants, though not premature, were underdeveloped, had very poor temperature control, and were prone to an obscure and deadly gastro-enteritis. French and Stare [8] say that in Rotterdam the infant-mortality rate rose from 126 in 1944 to 319 in 1945. (Incidentally, the 1944 rate is extraordinarily high; in 1938 it was 30.) On the whole, Smith's surprisingly negative findings are not in harmony with these parallel observations, but there is little or no information which contradicts him conclusively.

It is not easy to find a loophole in Smith's evidence, but certain theoretical possibilities should be considered, especially since studies of human famine cannot be repeated at will. One must assume that the Rotterdam clinical records, on which his main conclusions were based, referred to severely undernourished women. There is, however, no direct evidence on this point, though one would have expected clinical data to have been available, since women consuming considerably less than their basal requirements would be expected to show clear signs of starvation. Famine undoubtedly existed in the area [7–11]; but that women were less severely affected than men is suggested by the report [8] that the male death-rate in Rotterdam was 248 and the female rate 69% above the 1944 levels. The possibility that some pregnancies occurred without being reflected in the birth-rate does not seem to have been fully considered. While the incidence of amenorrhœa was about 50%, births fell to about one-third of normal. The presented evidence on abortions, which shows a decreased incidence, is admitted to be unsatisfactory. And although "stillbirth tends to be reported with some accuracy (as compared with the unsatisfactory information concerning abortions)" notifications may have been incomplete during a period of comparative civil disorganisation and widespread starvation, with its resultant apathy, especially since nothing could be gained by such reports. Established pregnancy, on the other hand, would probably be reported in all cases, in order to establish priority for rations; and hence it is disappointing that numbers of rationed pregnancies were not equated with numbers of births plus stillbirths. Such an equation might have revealed numbers of surplus pre which presumably would have ended in unrecorded carriage or stillbirth. Finally, in an account of kind it is desirable to know something of the condit under which hospital records were compiled by originators. Clinical accounts such as that of M hoven [7] indicate that at least some hospitals were exactly cases of calm routine, but shared in the ordinary hardships suffered by the population at Would statistics collected under such conditions entirely comparable with those of normal times, or the Rotterdam maternity hospital unusually fortunate? Though Smith doubtless considered this point, his on comment is that the records were "presumably accurate.

Other reports on the Dutch famine are said to be publication. They will be read with interest. while, Smith's findings underline the need for f study, but do not mean that statistics of mo connected with reproduction and infancy have little no bearing on the social and nutritional well-being populations.

DISTRIBUTION OF STREPTOMYCIN

SIR,—Your leading article of June 14 states that are some 2000 cases of tuberculous meningitis a and that the Government hope for a production perhaps 250 g. of streptomycin a month by next J enough to treat at most 50 of these 2000 cases. Y complacency, and the Government's, in the face of abject failure of nationalised medical care, does however, end there; for it is repeatedly suggested your columns and in Mr. Bevan's statements in House of Commons that the value of streptomycin pulmonary tuberculosis is still unproved, and that would therefore be unjustifiable to embark on expense of full production until the M.R.C. trials been completed. Yet it has already been shown competent American investigators that strepto will save the lives of most patients who have disease of the lungs or acute exudative disease. As that there are three times as many deaths from disease as from tuberculous meningitis, and a like n of deaths from acute exudative disease, there will some 10,000 or more deaths from tuberculosis next which could have been prevented by an adequate of streptomycin. Moreover, streptomycin is of greatest value as an adjunct to surgical procedures pulmonary tuberculosis, making for greater safety quicker healing; and even as a palliative measure it invariably be relied upon to lessen cough, reduce fe and improve well-being.

This complacency in all aspects of tuberculosis con- is of course of long-standing: thus in noting (in the issue on p. 837) the great success of the Minnes scheme in lowering the incidence of infection, you that it "is not as a whole applicable to centres in country." Why on earth not? Likewise, after 40 y of Government administration for tuberculosis, almost as long a period of Government control of production, we still have thousands of children inf and crippled by the bovine bacillus every year. If United States can eliminate tuberculous dairy c so that tuberculosis of bone and joint in children practically unknown, why cannot England do the s

Lest you should wonder why a cancer specialist sh write to you on tuberculosis, may I briefly recount following case?

In April last year a thoracoplasty was done for a cavity in the left upper lobe. Unfortunately the day the first-stage operation, atelectasis of the left lower ensued, and then tuberculous bronchopneumonia, began to stabilise some weeks later. In July, how after several attacks of unexplained pyrexia, a sk showed a hæmatogenous spread throughout the right On August 6, when the patient was practically mor- streptomycin was started; by the 16th cyanosis had appeared, fever had subsided, and appetite returned. 3 g. daily for 120 days the sputum became negative.

ear later, it would be impossible to tell from the skia- ns that the lungs had ever been infected with tuberculosis, omplete is the resolution not only of the right-sided ury disease and the exudative disease in the left lower , but even of the caseo-cavernous disease in the left r lobe.

you publish this brief case-history, it would be ng not to acknowledge with gratitude the extra- nary generosity and kindness which our American Canadian colleagues have shown to the stranger in their gates.

RALPH PHILLIPS.

mmit Park Sanatorium, Pomona, N.Y., U.S.A.

* Complacency about any side of the campaign nst tuberculosis would certainly be out of place. n sufficient expenditure, the disease is one that is rollable and ultimately preventable; but at present not being controlled. So long as this is so, there be some hesitation about diverting any large ortion of our limited resources to the development a expensive remedy which is promising rather than en. Our correspondent is, we believe, overstating incidence of the miliary and acute rapidly fatal lative forms of the disease, neither of which perhaps ommoner than tuberculous meningitis. As for ionary tuberculosis in general, caution will remain ssary until the merits of streptomycin have been demonstrated in an organised investigation. If eem to be carrying caution too far it is only because implications, and the hopes aroused, are so tre- dous. The largest possible trials are required, and a relief to learn that the amount of streptomycin produced in this country by next summer, though in relation to American output, is likely to be y greater than the 250 g. a month which was formerly aoned.—ED. L.

VISITING THE SICK

R,—I write in connexion with Miss Olive Matthew's r, published in your issue of Aug. 2.

r some years friendless inmates of public-assistance tutions and chronic-sick cases in hospitals under the C. and a few other authorities have enjoyed the ces of the Pen Friends Guild, whose members spond with old or sick folk who have no other act with the outside world. The pen friendships have resulted have been so greatly appreciated I am anxious to see the service extended, and should ery glad to hear from anyone who might be willing rganise a county branch of the guild. The work be undertaken even by busy people, since it can egulated in accordance with the time that can pared.

M. A. PRATT
Hon. Secretary, Pen Friends Guild.

view, Bryants Bottom, Great Missenden, Bucks.

LEUCOPLAKIA

R,—Leucoplakia vulvæ and kraurosis are very rare. oplakia is a precancerous condition, in which diagnosis is important. Leucoplakia, kraurosis, many of the maladies described in gynæcological ooks are usually vulvar dermatitis, associated with nplicating factor such as uterine, vaginal, or urethral arge. The whitish, macerated, horny epithelial seen with many of the dermatological conditions ting the anogenital region and surrounding area too often in the past been called leucoplakia. If word is retained, a better term would be "leuco- c vulvitis." In the late stage of vulvitis a degree ontraction occurs which has been mistaken for rosis.

me years ago[1] I described in detail several cases ved over many years, and at the request of omyns Berkeley I wrote an article[2] on the diagnosis treatment of these maladies, in which the work of ent dermatologists of Britain, France, Germany and ica was summarised.

uring twenty years the cases sent to me by gynæ- ists labelled leucoplakia could be placed under these headings—lichenification, eczema, intertrigo, tinea cruris, seborrhœic dermatitis, and eczematised psoriasis; or, less commonly, erythema multiforme, scleroderma, pemphigus, dermatitis herpetiformis, and lichen sclerosus.

I was interested to see from your annotation of July 26 that œstrin therapy has fallen out of favour; I long ago came to the conclusion that more rapid and enduring results were obtained by pelvic diathermy (Cumberbatch technique). Vitamin A is certainly of value, but with war-time diet it is difficult to appraise its effect when other remedies are also employed.

London, W.1. AGNES SAVILL.

A HYGIENIC FORK

SIR,—Dr. Gordon is doubtless bacteriologically right in condemning the present design of forks (Aug. 9, p. 220), but he cannot blame it on our ancestors. I happen, as I write, to be finishing my breakfast with an 18th-century fork. It has three prongs, no ridges of any kind, and the business part glides into the handle with a rounded smoothness which knocks spots off Dr. Gordon's bevelled *edges.* Also, a small point, it looks beautiful, which is more than can be said for Dr. Gordon's drawing.

Oxford. E. M. VAUGHAN WILLIAMS.

BOARDS AND MANAGEMENT COMMITTEES

SIR,—The regional hospital boards must soon decide the principles which are to guide them in the appointment of hospital management committees and their officers. The sources from which any bodies are renewed —or, in the Churchillian phrase, "refreshed"—determine their strength and vitality; and future membership of the boards, at least on the lay side, will no doubt go to those who distinguish themselves on the hospital management committees. When we come to the actual recruitment of the management committees, however, we have less grounds for confidence.

It seems to me that your leader of July 12 hardly goes far enough. It is in effect a powerful plea that the management committees should have a dominant voice in the selection of their members. The committees of voluntary hospitals are at present largely composed of those who work or pay, or perhaps do both. Justification by works is an excellent credential for any man, but will this method of selection necessarily prove adequate in the new conditions? Some hospital committees seem to be out of touch with the broad currents of local life, and while this was a serious enough defect under the old system it may prove disastrous under the new. The regional boards of the future will require to be broad-based on the hospital management committees, and the proper manning of these may ultimately make or mar what the Minister is the first to admit is an administrative innovation. It is to be hoped therefore that both regionally and locally there will be a sustained effort to keep the membership of the committees in full and continuous contact with the life of the communities they serve.

And what of regional administration? You speak of global budgets instead of itemised control. So far so good; but what is to be the guiding principle in determining the size of the regional budget? Will this be based on the population of the region, or on the number of existing hospital beds; and will the development budget be determined on the bed deficiencies? Having determined the size of the regional budget, how is this to be apportioned by the board? The boards have responsibility for the acts of the hospital management committees to which they delegate many of their powers. What will happen to the management committee which overspends its appropriation? The only remedy for wilful default in this matter appears to be the supersession of the committee.

The regional boards will no doubt set out determined to afford the widest degree of autonomy possible to the management committees. But the committees are to appoint and dismiss staff, not in their own name, but in that of the regional board, which will be in a contractual relationship with the staff concerned. Is it fanciful to see in this arrangement a potent source of difficulty and embarrassment?

Complaints are of first-class importance in any organisation. From them administrators learn the day-to-day lessons of their job. Failure to deal adequately with complaints is probably the greatest source of irritation to the consumer, and much of the impatience displayed in dealing with large institutions arises from the apparent lack of satisfaction given to complainants. A hospital management committee is the agent of a board. *A justified complaint against a hospital may be* the measure of the committee's failure adequately to discharge their responsibilities. Are they always to be judge and jury in their own case, and is a board to deprive itself of the educative value of handling complaints? Sooner or later the Minister must be involved, as he is at the present time—but with the cardinal difference that in the future he will have the final responsibility to the public. The regional boards cannot be content to act merely as a channel of communication between the central authority and the hospital management committee, nor to accept, without question, explanations which may ultimately reflect on the manner in which their obligations have been discharged.

When the boards become responsible for the hospital finance of the region there will fall to them the invidious task of attempting to iron out inequalities of wages and salaries and conditions of service generally. Moreover in times of general shortage of both goods and services the boards cannot allow the individual institutions to compete with each other and to compel a rising scale of costs at the expense of the regional budget.

The chief criticisms against the existing hospital services, apart from the inequalities of provision and lack of overall planning, are to be found at either end of the scale. The larger hospital authorities have been criticised for their bureaucratic tendencies and the smaller hospitals for having parochial outlook and being in some cases a vested interest. It seems that there will be an impetus towards compelling the regional boards, in sheer self-protection, to limit the degree of delegation which every fair-minded observer would like to see granted to the hospital management committees.

The whole success of this great venture may therefore depend firstly on securing that the committees attract and recruit their members from the widest field, and in their administration strike a nice balance between centralisation and devolution. To do this will require their unceasing vigilance, and they will have the right to expect that the *management committees are* sympathetic to the great difficulties with which they will be confronted.

Southend-on-Sea. J. STEVENSON LOGAN.

ÆTIOLOGY OF DISSEMINATED SCLEROSIS

SIR,—Your annotation on July 19 contained a quotation from the paper of Kabat, Wolf, and Bezer on the production of brain lesions by injections of heterologous brain tissue with "adjuvants" into monkeys. The lesions are described as perivascular polymorphonuclear infiltration associated with œdema, degeneration of myelin, and occasionally fresh hæmorrhages.

In my experimental work on heat-stroke I found lesions similar to these, except that hæmorrhages were absent, in the brains of many rabbits after subjection to hyperthermia. My experiments are referred to very briefly in the *British Encyclopædia of Medical Practice*, Cumulative Supplement, 1947, p. 127; I have not yet had time to publish them in full. Microscopic *hæmorrhagic* lesions in the brain after hyperthermia have been described by Hartman [1] and others.

It is possible that the brain plus "adjuvants" injected by Kabat et al. may act as foreign protein and cause the animal to become pyrexial, even hyperpyrexial. I was puzzled to explain the lesions in my experimental material: I thought the changes might be due to a combination of hypoxia and ischæmia; an immunological explanation did not occur to me. The blood of hyperthermic animals inclines to a relatively low pH due to outpouring of lactic acid from the heated and oxygen-starved tissues, principally muscles. Many years ago Suzman (in a paper in the *British Journal of Experimental Pathology*) showed that emulsions of brain tissue added to saline suspensions of *killed bacterial cultures* produced agglutinins of very high titre in the blood of rabbits after subcutaneous injection. The explanation then given was that the brain emulsion caused rhythmical contractions of the spleen. The brain emulsions used were highly diluted and autoclaved before injection.

Under the circumstances it is rather curious that the effective treatment employed by Prof. P. O. P. Clarke should be repeated T.A.B. pyrotherapy.

Epping. FRANK MARSH.

ELECTRONARCOSIS

SIR,—The report by Dr. Spencer Paterson and Dr. Milligan (Aug. 9) holds out hope that electronarcosis may prove another useful treatment in psychiatry. I have just returned from a visit to the U.S.A., where I found opinion still much divided on its value. It probably be some time yet before we know its p use in relation to the present established methods treating schizophrenia.

Meanwhile there is a real danger to be guarded When electric convulsion therapy was first introd *it was too rapidly suggested as* a possible simpler stitute for insulin. This had unhappy results for patients who were given it instead of insulin in the recoverable stage of their illness. Findings now s that some drifted into chronicity as a result.

I do hope therefore that electronarcosis will not used too widely as a substitute for insulin till fin as to their relative values are fairly certain. Now machines are becoming more easily available for our we do not wish for a repetition of the E.C.T. tr. To allow a schizophrenic to drift into avoidable c may mean thirty years' suffering for the patient and large financial burden to the relatives or the State.

Sutton Emergency Hospital. WILLIAM SARGANT.

ACTINOMYCOSIS OF RECTUM

SIR,—In connexion with an investigation which I making into the incidence and symptomatology actinomycosis involving the rectum and anus, I be greatly obliged if any of your readers would let have details of any such cases which may have under their observation.

London, N.W.3.

V. ZACHARY CO

ADMINISTRATIVE RESPONSIBILITIES OF TH MATRON

SIR,—May I correct the statement of your spondent of July 26 (p. 147)? The Association of H Matrons drew up, in 1945, "suggested standing for matrons" which were intended to help indi hospitals to compose their own, as the first p stated. It has been no part of the policy of the A *tion to lay down regulations or* standing orders hospitals; we have merely offered helpful su Contrary to the impression of your correspondent, association had in mind every kind of hosp voluntary, municipal, and private. Since these different practices, main principles only were set for adaptation and amendment to suit the require of each. Suggestions were also made for procedure be followed when the office of matron became vacant

This association does recognise that the h governor, secretary, or medical superintendent, as case may be, is the chief executive officer of the h and that the closest liaison on administrative is necessary between himself and the matron at all t Professionally she is head of the nursing staff, but problems arise she should consult with the chief ex officer. There are still, however, hundreds of hos in this country where the matron carries out the d of the chief executive officer as well as her own; difficulties have mainly arisen in such hospitals whe chief executive officer has been appointed, and, wit any explanation on his part or the part of the com has taken over the duties, and has totally disregarded proper professional standing of the matron.

Certainly the matron should be capable of cooperation with the other departments of the hos that is one of our recommendations.

E. COCKA
Hon. Secr

Association of Hospital Matrons.

Parliament

ON THE FLOOR OF THE HOUSE

HE crisis turned what was to have been a short k with an adjournment motion for the recess into a long week. On Bank Holiday Monday after an iustive debate on Germany and Austria we went on inish with the Agriculture and the Transport Bills did not rise till 6.45 A.M. on Tuesday.

ie Government have stated that after the end of current period Great Britain cannot continue to in dollars for supplies to the German people. They also been forced to impose heavy taxation on ywood films. It is hard, concrete, ungetoverable ulties of this kind which may be part cause of the ig out of the original Marshall "plan" into a nebu- Marshall "suggestion." The original proposal was cted to bring help to Great Britain by the end of and before the adjournment of the American ress. But, as Mr. Attlee made clear in his speech ie Commons, it is impossible for this country to ne permanently dependent on the U.S.A.; and ress has adjourned till January, 1948, with no offer is country.

ie programme of austerity announced in the debate ednesday and Thursday on the state of the nation price of British freedom, and the Battle of the Gap i. Many expedients for reducing our expenditure considered, including a heavy cut in our Armed es. A reduction by half was in the minds of many ibers. And some bigger reduction than at present ested may have to be made, because expenditure iem is one of the biggest items of our budget. We ot cut down essential basic foods, although we can must cut luxuries. We must produce more and rt more, and this we cannot do if the workers are well enough fed.

is expected that the Paris consultations on the hall offer will consider the possibility of an economic ration of the western European countries there sented. In the crisis debate it was suggested that integration should extend to the agricultural countries astern Europe—in particular Hungary, Roumania, oslavia, and Czechoslovakia—and beyond that to Soviet Union. It is significant that arrangements since been announced with Hungary for supplies acon, eggs, and fats. Those M.P.'s who are also omists think the days of the old free multilateral is over and that regional arrangements must ce them. The North and South Americas make such region. The British Commonwealth with the nies makes another. Add to the resources of the h Commonwealth those of continental Europe and Soviet Union and you have a region potentially as s the two Americas. It is considerations such as these are the daily bread of Parliament at present. And o vast economic changes in production and trade that vernments must look forward. The crisis is not that itain alone; it is the growth of a new world out of ld, and the new forces are at work under our eyes.

MEDICUS, M.P.

FROM THE PRESS GALLERY

Tribute to the Indian Medical Service

the House of Lords on Aug. 7 the Earl of OWEL, in the course of moving an appreciation ie work of the civil and military Services of the n in India, said that the Indian Medical Service, gh its primary function had been the care of these ices, had also contributed substantially to the nce of medical science and had played a leading in building up a modern system of applied medicine dia. Its research into the cause of malaria resulted liscoveries about the malarial mosquito which led the Panama Canal to be built. In the applica- of medicine it reduced the death-rate from cholera dia by two-thirds, and its mastery of the diagnosis treatment of many tropical diseases had brought to thousands of victims. It was the pioneer, for many years the only source, of medical education, the father of the three medical colleges which were ded in British India in the nineteenth century. The result of the pioneer work done by the I.M.S. was that India now possessed a well-organised medical profession of more than 50,000 practitioners. The PRIME MINISTER, moved a similar resolution in the Commons.

Medical Practitioners and Pharmacists Bill

In answer to a question, Mr. H. MORRISON stated that this Bill had been published in order that the House and the country should be aware of its proposals. It was not proposed to proceed with it this session.

School Medical Services

In introducing the estimates for the Ministry of Education in the House of Commons on July 31, Mr. TOMLINSON said there were some 5 million children in the schools, but among that large family there were 75,000 handicapped children—only $1^1/_2\%$ it was true, but the nation would be judged as much by what it did for the $1^1/_2\%$ as by what it did for the $98^1/_2\%$. Therefore, he was pleased that in dealing with the problem of the handicapped child some progress had been made in the Ministry's specialist organisations and services.

The rise in the number taking milk in schools had been remarkable. In June, 1946, it was 3,370,000, or 72%; in June, 1947, when milk was free, it was 4,300,000, or 92%. Of all milk given in schools, 94% was either heat-treated or tuberculin-tested. About 50% of the school-children today were receiving meals in school: more progress could have been made but for the decision to put the provision of huts in preparation for the raising of the school-leaving age before the feeding of children.

QUESTION TIME

Consumption of Foods in 1946

Mr. P. FREEMAN asked the Minister of Food what was the total weight and value of all principal foods consumed in this country in 1946; and the corresponding details for foods supplied to restaurants and canteens, separately—Mr. J. STRACHEY gave the following figures:

	Total food		*Catering establishments*	
	Quantity '000 tons	Value (*a*) £'000	Quantity (*b*) '000 tons	Value (*c*) £'000
Bread	4,415	101,638	503	10,941
Flour	1,753	33,887	89	1,946
Cakes and biscuits ..	1,113	150,104	107	13,201
Meat and offal (*d*) ..	1,814	211,347	182	21,140
Canned meat	172	32,229	15	2,667
Bacon and ham (*e*) ..	306	57,255	21	3,416
Fresh fish	1,072	81,591	—	—
Butter	229	40,957	20	3,337
Margarine, lard, and cooking fat	504	39,877	58	4,292
Fresh milk (*e*)	6,700	207,798	959	28,799
Canned milk	166	14,026	17	1,337
Dried milk	42	8,205	3	224
Cheese	218	25,983	20	2,118
Eggs in shell (*e*) ..	201	27,054	—	—
Dried egg	37	17,719	5	2,274
Tea	191	63,328	32	10,129
Sugar	1,254	49,506	92	3,155

Chocolate and sugar confectionery ..	232	49,529	24	4,136
Potatoes	5,502	60,225	—	—
Vegetables	2,265	116,844	—	—
Canned and dried vegetables	349	25,660	—	—
Fresh fruit	985	95,518	—	—
All other foodstuffs..	—	178,875	—	69,582
	—	1,722,746	—	185,495

(*a*) These values are the totals of the estimated expenditure in the following five categories:

(i) Domestic purchases of food by households at retail prices, together with the value at farm prices of produce consumed on farms, and the value at the cost to the consumer of welfare foods provided under the National milk, milk-in-schools, and vitamin schemes.

(ii) Purchases by category A catering establishments (restaurants, hotels and all residential establishments, together with institutions such as Services hospitals, orphanages, and hostels, and school canteens and feeding centres, war-time nurseries, and public and private day schools) valued at the prices paid by these establishments.

(iii) Purchases by category B catering establishments (voluntary services canteens, fire and police canteens, industrial A and B canteens, youth service centres, workers recreational clubs, and all other cadet clubs, &c.) valued at the prices paid by these establishments.

(iv) Purchases by the Services of food for the Armed Forces in the U.K. valued at the prices paid by the Services.

(v) The quantities of ingredients used for the production of manufactured foods and their value at the prices paid by manufacturers are included against the ingredients where these are given separately in the above table. The value of other ingredients and the added value resulting from manufacture are shown against all other foodstuffs.

(*b*) The quantities of unrationed foods consumed in catering establishments are unknown. An estimate of their value is included in the total. (*c*) These values represent the totals of groups (ii) and (iii) noted in (*a*) above. (*d*) Including canned corned meat and pork self-suppliers. (*e*) Including self-suppliers.

Poliomyelitis

Asked by Mr. E. FLETCHER whether any general direction has been given for closing swimming-baths in districts where poliomyelitis occurs, Mr. A. BEVAN, Minister of Health, said: I am exceedingly anxious not to create an atmosphere of panic. It must be remembered that sad and calamitous though the consequence of this infection often is, there are very many other epidemics which are very much more serious, and we must keep a sense of proportion. I believe that the psychology of panic would be far worse than the advantage of any directions that I would be able to give.

Mr. G. NICHOLSON: While I accept and agree with what the right hon. gentleman has said, does he not think it would be advisable for his department to make such statements on the disease in order to allay anxiety and to tell parents how best to try to avoid sources of infection? Surely a little guidance is needed.—Mr. BEVAN: I have already given guidance, and general information has been given from the beginning. I must warn the House against frightening parents unnecessarily.

In further answers Mr. BEVAN said there was no evidence whatever of the slightest connexion between malnutrition and infantile paralysis. Research on this, as other virus diseases, was at present a matter for the Medical Research Council.

Colonel M. STODDART-SCOTT asked the Lord President of the Council what public money was being spent on research into the causes, prevention, and treatment of infantile paralysis.—Mr. H. MORRISON replied: Research on virus diseases, of which infantile paralysis is one, forms an important part of the programme of the Medical Research Council, and over £10,000 is being spent upon it in the present year. The proportion of this represented by the salaries of workers devoting most of their time at present to studying infantile paralysis is about £2000.

Homes for Aged Persons

Mr. F. MESSER asked the Minister of Health if he was aware that some voluntary organisations were deferring the setting up of homes for old sick people owing to their doubt as to whether such homes would come under the regional hospital board; and if he would make clear the position of such non-profit-making establishments.—Mr. BEVAN replied: I know that doubts have been expressed. The position is that if a non-profit-making home exists to provide medical or nursing care for old sick people it in future becomes the responsibility of the hospital service, unless specially disclaimed by me. This does not mean that a home existing for the aged non-sick is precluded from arranging minor facilities for minor ailments, or, for example, the periodic visiting of a doctor. But if it becomes a place whose function is essentially the care of the sick the position is as above.

Penicillin for Germany

In answer to a question, Mr. C. P. MAYHEW stated that in May, 1947, the issues of penicillin to the British zone from official sources in mega units were: for venereal-disease cases, 1271, and for non-venereal-disease cases, 100. An additional 2000 were issued from non-official sources for non-venereal-disease cases. In August 5000 mega units will be available from official sources.

Recruitment of Nurses

Mr. A. L. SYMONDS asked the Minister of Health if he had now given consideration to the practical effect on recruitment to the nursing profession, on the Rushcliffe scale of salaries, of recent judgments of magistrates at Clerkenwell and Wealdstone.—Mr. BEVAN replied: I understand that this matter is being taken to the High Court.

Health Education Films

Mr. G. COOPER asked the Minister if he would consider sponsoring a British film through the Central Office of Information, for use in senior schools and for the education of the public in childbirth and maternal and child welfare including the work of antenatal clinics.—Mr. BEVAN [illegible] The Ministry of Health has already produced, through Central Office of Information, a series of films on the of young children. Others on various aspects of m and child welfare are in production or planned.—Mr. COOPER: Does the Minister realise the extraordinary [illegible] human interest taken in an American film which being shown at a cinema in the Charing Cross which has attracted very great crowds? Does he not t that it is important to show the public of this country British practice as distinct from the American practice? Mr. BEVAN: We are indeed showing a large number English films. I would resist any inclination to believe the Americans in this matter are more forward than we are.

Colonel STODDART-SCOTT: Will the Minister p the House that he will not have shown in senior schools film which shows a detailed, factual and faithful repro of the operation of childbirth, which can only have a det effect, ultimately, on the birth-rate? Mr. BEVAN: I am that the Minister of Education and I will bear in mind technical advice we have on this subject, but the effect on psychology of the child seems to be a matter upon laymen have as much information as specialists.

Fruit Content of Jam

Sir E. GRAHAM-LITTLE asked the Minister of whether he would make it clear to the public that full fruit standard of English jam contained only 10% the fruit specified on the label, the other contents extraneous matter.—Mr. STRACHEY replied: hon. Member is mistaken in thinking that any full standard jam contains only 10% of the fruit specified on label. In no case may the fruit content be less than [illegible] The only other ingredients that may be used are sugar, and, where necessary, traces of colouring matter and servative. I do not regard any of these ingredients as the normal meaning of the term "extraneous matter," they are essential to the best manufacturing processes.

Obituary

JOHN SCOULER BUCHANAN

M.B. GLASG., F.R.F.P.S.

Mr. Buchanan's death, on July 23, at the age of came as a shock to colleagues and friends. Last mo apparently in his usual good health, he attended Oxford meeting of the Association of Surgeons; on his return to Glasgow he developed a mild c attack which was followed in a fortnight by a recurrence.

A son of the late Dr. John A. Buchanan of Ruth he qualified at Glasgow in 1912 and served as h surgeon and house-physician in the Western Inf Having decided on a surgical career his next step to spend some months in general practice. War b out soon afterwards, and apart from a short period home service in 1915 he was in France and from the autumn of 1914 until 1918, serving as a surgical specialist. When hostilities ceased he transferred to Glasgow as orthopædic surgeon to Bellahouston Red Cross Hospital, and in 1919 he elected to the staff of the Western Infirmary wh joined the clinic of the late Mr. Archibald Young 1925 the death of Sir William Macewen led to Yo promotion to the regius chair of surgery, and Buch became his university assistant. A few years later became senior assistant to the late Mr. Farquhar Ma in the Western Infirmary, and after Macrae's retire he held a similar position with Mr. W. A. Camp In 1936 he was promoted visiting surgeon and two later became hon. lecturer in surgery in the univers Thus throughout his professional career he held app ments in the Western Infirmary; but in his ye days he was also for 10 years assistant surgeon to Royal Hospital for Sick Children, and for the la years of his life he was consulting surgeon to Ayr C Hospital. A devoted fellow of the Royal Facu Physicians and Surgeons of Glasgow, he was c visitor in 1946, in which year he was also elected to council of the Association of Surgeons of Great Br and Ireland. He did more than his share of public and at the time of his death was a member of the anagement of the Western Infirmary and of the l Maternity Hospital and was chairman of the sory committee of the staff of the Western Infirmary. vas a good committee-man and his advice was highly ed.

ichanan excelled as a general surgeon and had a private consulting surgical practice. Patients ed him without reservation; for here, they knew, a man full of human sympathy yet master of the tion. He was thorough in the pursuit of an accurate perative diagnosis, and, having taken his decision, ld operator. He taught and practised meticulous and post-operative treatment, and he was rewarded brilliant results in very diverse fields of surgery. a teacher, too, he achieved outstanding success. had an inquiring and critical mind and an nsive knowledge of surgical literature; he pre- d carefully; he delighted in the giving of instruction he understood students and their difficulties. With ergraduates and postgraduates alike he was one of nost popular surgical teachers in the West of Scotland. erved for a term of years as examiner in surgery to University of Glasgow and as examiner for the wship of the Royal Faculty. In this he was thorough conscientious, and many a candidate has had occasion e grateful for his unexpected patience. He did not ve in writing unless he had something of real value ut on record. His few publications are marked by clarity of expression and careful preparation which e characteristic of the man.

Scouler" was an asset at any gathering whether ical or lay. He was a "good mixer" and had a of friends. He was a keen sportsman, a good shot, an enthusiastic angler, and he greatly enjoyed a on the golf-links. He was kindly and courteous ever ready to help those in trouble. He was taking ncreasing place in the councils of the profession in land and his untimely death at the zenith of his er is a loss which we can ill afford. His wife, a ghter of the late Mr. John H. Hair, of Lossiemouth, his most devoted helper in all his many activities, of their two children his son is a recent Cambridge lical graduate.

W. W. G.

Births, Marriages, and Deaths

BIRTHS

N.—On Aug. 6, in London, the wife of Dr. E. H. Allen—a son.

Y.—On Aug. 7, the wife of Dr. Charles Carey—a son.

KMAN.—On Aug. 1, at Johannesburg, the wife of Dr. Jonathan Gluckman—a daughter.

RISON.—On Aug. 7, at King's Lynn, the wife of Mr. John O. Harrison, F.R.C.S.—a daughter.

Y.—On Aug. 6, in London, the wife of Dr. R. A. Hoey—a daughter.

HES.—On Aug. 8, the wife of Dr. W. Hughes—a son.

S.—On Aug. 1, in Singapore, the wife of Dr. D. N. Keys—a son.

UEEN.—On Aug. 4, at Sydney, Australia, the wife of Dr. E. G. McQueen—a son.

RENSHAW.—On Aug. 2, at Esher, the wife of Dr. Gerald Ollerenshaw—a daughter.

LS.—On Aug. 1, at Ipswich, to Dr. Dorothy Wells, wife of Dr. J. M. W. Wells—a daughter.

MARRIAGES

RIDGE—RADCLIFFE-WILSON.—On Aug. 2, at Crondall, Reginald Aldridge, M.R.C.S., to Anne Margery Radcliffe-Wilson.

KETT—CHALMERS.—On Aug. 7, at Northants, David John Crockett, M.B., to Anne Baillie Chalmers.

STER—WATT.—On Aug. 4, at Aberdeen, John Scott Inkster, M.B., lieutenant, R.A.M.C., to Helen Milne Watt.

RIS—GARLAND.—On Aug. 10, in London, David Morris, M.R.C.S., to Netta Garland.

—TUNSTALL-BEHRENS.—On July 23, in Cornwall, Kenneth Till, M.B., to Morwenna Tunstall-Behrens, M.B.

DEATHS

TS.—On Aug. 6, at Worthing, Claude Alexander Birts, M.B. Lond.

WOOD.—On Aug. 3, 1947, at Lagos, West Africa, Dorothea Elsa Garwood, M.R.C.S.

INGTON.—On Aug. 4, at Bristol, Cyril Claude Lavington, M.B. Durh., aged 67.

EY.—On Aug. 4, at Penzance, Reginald Oliver Sibley, M.D. Lond. D.P.H., D.T.M., aged 75.

TKIN-WILLIAMS.—On Aug. 5, at Padstow, Penrose Lanyon Watkin-Williams, D.S.O., F.R.C.S., aged 79.

D.—On Aug. 7, at Cheltenham, Oliver Hilton Wild, M.B. Edin., aged 63.

OD.—On Aug. 9, at Bournemouth, Charles Wood, M.R.C.S., J.P., aged 90.

Notes and News

TRANSITIONAL ARRANGEMENTS FOR HOSPITALS

When the National Health Service comes into operation on July 5, 1948, the day-to-day management of hospitals, other than teaching hospitals, will rest with the hospital management committees. These committees, however, are unlikely to be appointed until the early part of next year, and in the few months before they assume responsibility they may find it hard to arrange for certain services—such as supply, accounting, and the maintenance of premises and land—which are at present provided by local authorities for large groups of institutions. The Ministry of Health therefore proposes (circular 134/47) that where such an arrangement seems desirable, the local authorities should be asked to continue such services for an interim period (initially nine months), acting for this purpose as the agents of the regional hospital boards. Officers engaged in such work would be transferred to the regional boards as provided by the Act, but would remain for the time being with the local authorities now employing them.

BETTER PAY FOR PART-TIME NURSES

The rates of pay of part-time nurses, and especially those offered to volunteers who have had previous nursing training or experience, have been widely criticised. Some authorities are paying them 1*s.* 5*d.* an hour, according to the Rushcliffe scale; but the Ministry of Health note (circular 124/47) that these rates will need to be reviewed in the light of the report of the working party on the recruitment and training of nurses. In the meantime, the Ministry suggests, 1*s.* 9*d.* an hour might, in many cases, be appropriate. A woman who holds a certificate of three years' training issued by a hospital before July, 1925 (and who therefore might have been put on the State register had she applied in time) might be offered 2*s.* an hour.

These increases indicate that the poor pay of nurses generally, and of part-time nurses in relation to that of other part-time workers, is beginning to receive serious consideration in the proper quarters.

STREPTOMYCIN IN ITALY

In Italy, Fontana and Roversi[1] have treated four cases of tuberculous meningitis with streptomycin and they give a preliminary report on the results. The first patient was a man of 26, admitted to hospital on Jan. 27 with the typical cerebrospinal fluid (C.S.F.) and clinical picture—neck-rigidity, photophobia followed by optic neuritis, and paresis of urinary bladder and lower limbs. He was given nine injections of streptomycin 50 mg. intrathecally and three-hourly intramuscular injections of 50 mg. to a total dosage of 7 g. He gradually improved, and after 35 days in bed was discharged from hospital on March 3 with slight residual paresis and almost complete blindness of the left eye. The C.S.F. was then "almost" normal. The second patient, admitted seriously ill on Feb. 16, was showing considerable improvement with streptomycin when the supply of the drug failed; he died $2^{1}/_{2}$ months later. In this case streptomycin was injected in small doses, usually 50 mg., both intrathecally and intramuscularly, but with interruptions (probably due to irregular supplies) which are said to have clearly shown the beneficial effects of the drug over a period of a few weeks. In the third case streptomycin was started on April 1, and the patient at first showed considerable improvement, but two months later he was getting worse. The fourth patient was admitted unconscious and delirious on May 14. With streptomycin he made a remarkable recovery and is still progressing well. Fontana and Roversi conclude that the small doses they used have given results not inferior to those of the large doses used in America. Their cases certainly deserve to be reported in detail, with a follow-up record of the two which seemed to respond favourably to this very low dosage.

School of the Royal Free Hospital

The title of the London (Royal Free Hospital) School of Medicine for Women has been changed to the Royal Free Hospital School of Medicine. In the coming session men students are to be accepted at the school for the first time.

---

1. Fontana, L., Roversi, A. *Minerva med.* 1947, ii, 29.

University of Cambridge

A bequest of £1000 for research in pathology has been received by the university under the will of the late Dr. Louis Cobbett, formerly University lecturer in pathology.

A secretary is to be appointed to the medical school; the general board recommends that his salary should be £600–800 a year.

University of London

LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE.—The following students from the school were successful in the recent examination of the Conjoint Board for the D.T.M. & H.

G. M. Abraham, J. F. Britto, J. H. Cater, K. H. Cheung, S. Childs, L. M. B. Copland, M. A. C. Dowling, A. J. F. Eberle, E. N. Emmerson, Z. A. Fazelbhoy, S. K. Ganguli, V. T. H. Gunaratne, M. T. Gyi, V. W. D. Hall, W. D. Hughes, J. P. F. Hummel, M. P. Hutchinson, F. C. Kerr, S. Khayatt, S. N. Kothare, N. W. Low, P. C. Mahanty, B. K. Naik, A. A. Odler, A-H. A-R. Omar, C. P. Patel, D. N. Patel, A. J. Patterson, R. A. O'G. Pearson, J. G. Salter, J. P. Satterwhite, R. S. Saxton, J. C. Shee, R. P. Shields, K. G. B. Stork, R. Symons, S. W. W. Terry, W. F. J. M. Thom, E. Tuckman, H. W. Wheate, H. H. Wozniak, G. B. Wright; and, in part B under old regulations, K. P. Hare. The Lalcaca medal and the William Simpson prize, awarded to the best student of the year, have been won by Dr. Henry S. Fuller.

University of Manchester

Dr. Andrew Topping has been appointed professor of preventive medicine and director of the department of preventive medicine. He will take up his duties in November.

Dr. Topping was educated at Robert Gordon's College and the University of Aberdeen, where he graduated M.A. in 1911, M.B. in 1915, and M.D., with commendation, in 1923, when he also obtained the diploma in public health. He became M.R.C.P. in 1942, and was elected to fellowship last year. From 1914 to 1919 he served with the R.A.M.C. in France, Gallipoli, and Mesopotamia, and was mentioned in despatches. After a period as senior medical officer and port health officer at Abadan in Persia, he was successively R.M.O. at the Aberdeen Fever Hospital, assistant M.O.H. for Woolwich and for Lancashire County Council, M.O.H. for Rochdale, medical superintendent of the London County Council Southern Fever Hospital, and deputy M.O.H. for the County of London. In 1944 he was appointed director of the health division of UNRRA, European office, and later he became deputy chief of relief services in the same office, from which post he has lately retired. He has been a lecturer in public health for five years at Charing Cross Hospital medical school. He has published papers on smallpox, maternal mortality, hospital administration, and European health problems, and with Sir Archibald Gray made the Regional Hospital Survey of London.

Royal College of Surgeons of England

The first meeting of the board of the faculty in dental surgery of this college was held on July 31. The members of the board are as follows:

Sir Alfred Webb-Johnson, Sir Cecil Wakeley, and Mr. L. E. C. Norbury (as president and vice-presidents of the college), Mr. H. A. Mahony, Prof. H. F. Humphreys, Prof. H. Stobie, Prof. F. C. Wilkinson, Mr. Alan Shefford, Mr. W. Kelsey Fry, Mr. V. A. F. Greenish, Dr. E. W. Fish, Major-General A. B. Austin, Prof. T. Talmage Read, Surgeon Captain J. T. Wood, Mr. W. G. Senior, Mr. H. T. Roper Hall, Mr. Edward Samson, Mr. A. C. Deverell, Air-Commodore G. A. Ballantyne, Mr. F. S. Warner, Prof. R. V. Bradlaw, Mr. W. Leslie Boness, Mr. A. C. McLeod, and Mr. C. L. Endicott. Professor Bradlaw was elected the first chairman of the board.

The board expressed its appreciation to the council of the college in creating the faculty of dental surgery and establishing the fellowship in dental surgery (F.D.S.).

The following surgery lectures will be delivered in October, at 5 P.M. on each day: 1st, Prof. Ernest Finch, The Cancer Problem; 2nd, Mr. Harold Edwards, Treatment of Hernia; 3rd, Prof. R. Milnes Walker, Surgery of the Pancreas; 6th, Mr. N. R. Barrett, Neoplasms of the Lung and their Treatment; 7th, Mr. Lawrence Abel, Surgery of the Œsophagus; 8th, Mr. G. F. Rowbotham, Head Injuries; 9th, Mr. A. M. A. Moore, Surgery of the Tendons; 10th, Prof. J. R. Learmonth, Surgery of Portal Hypertension; 13th, Prof. Ian Aird, Surgery of the Biliary System; 14th, Mr. C. E. Shattock, Appendicitis; 15th, Mr. Grant Massie, Neoplasms of the Colon; and 16th, Sir Stanford Cade, Cancer of the Mouth.

The following lectures in anæsthesia are to be delivered at 6.15 P.M. on dates in October: 6th, Dr. H. J. Brennan, Endotracheal Anæsthesia; 7th, Dr. A. D. Marston, Pro-anæsthetic Treatment; 8th, Dr. C. Langton Hewer, Anæsthesia for Thoracic Surgery; 9th, Dr. T. Cecil Gray, *d*-Tubocurarine Chloride and its Use in Anæsthesia; 10th, Dr. John Gillies, Present Status of Volatile Anæsthetic Agents; 13th, Dr. W. W. Mushin, Signs of Anæsthesia; 14th, Dr. Mushin, Spinal Analgesia; 15th, Dr. E. A. Pask, Resuscitation; 16th, Dr. Bernard Johnson, Intravenous Anæsthesia; 17th, Dr. Massey Dawkins, Epidural Analgesia; 20th, Dr. Robert Cope, Anæsthesia for Babies and Children; and 21st, Dr. Vernon Hall, Postanæsthetic Treatment.

University College, London

Two lectures on the Structure of Peripheral Nerve and Nerve Endings are to be delivered by Prof. J. Z. Y— F.R.S., in the physiology theatre of the college at 5.15 on Tuesdays, Oct. 7 and 14. A course of six lectures Transmission of Excitation in Nerve and Muscle w given by Dr. Bernard Katz at 5.15 P.M. on Tuesdays Oct. 21 to Nov. 25. A further course of six lectures is t given at 5 P.M. on Wednesdays from Oct. 8 to Nov. by Mr. M. H. Pirenne, D.SC.; his subject will be Physiological Mechanisms of Vision.

Future of Stracathro Hospital

Stracathro Hospital, near Brechin, which was set up by Department of Health for Scotland to deal with war ca is to remain a general hospital with special provisi orthopædic and rheumatic cases, cases from the school service, and children suffering from debility and malnut The hospital is not to be used at present for cases of pulm tuberculosis.

The Society of Radiographers has applied for a c incorporation.

Dr. H. W. Wade, *president of the International* Association, has arrived here to make arrangements the International Leprosy Congress which is to be held Cuba between April 3 and 11, 1948. The last congress held in Cairo in 1938.

The third edition of the *National (War) Formul* to come into operation for National Health Insurance p on Oct. 1.

REGISTER OF DIETITIANS.—The third edition of this has now been published by the Board of Registratio Medical Auxiliaries. Copies may be had, free of charg the registrar, Tavistock House North, Tavistock London, W.C.1.

Appointments

ANDERSON, L. G., M.D. Lpool, D.P.H.: M.O.H., Exmouth, Salterton, and St. Thomas, and asst. county M.O.H.,

FECTIVE ENDARTERITIS OF THE PULMONARY ARTERY

Rae Gilchrist
din., F.R.C.P.E., F.R.C.P.
PHYSICIAN

Walter Mercer
M.B. Edin., F.R.C.S.E.
SURGEON

THE ROYAL INFIRMARY, EDINBURGH

ECTIVE endarteritis of the pulmonary artery is the onest and most serious complication of persisting y of the ductus arteriosus; yet many experienced ns and competent pathologists are unfamiliar t. In a series of 60 consecutive cases of patent observed during the past six years, infective eritis developed in 6 patients. The rapid develop- of successful methods of treatment of this hitherto uniformly fatal disease justifies the consideration n as small a group of cases as this. It is with the ion of clarifying the diagnosis and with the hope ablishing principles of treatment adaptable to lual requirements that the following remarks are ted.

NATURE OF THE LESION

an isolated defect the patent ductus is one of the common congenital malformations, often appar- harmless but liable at all ages to give rise to mary endarteritis, which is the local manifestation eneral septicæmia, similar in its ætiology, pathology, course to the better-known subacute bacterial arditis commonly engrafted on an old rheumatic lar flaw. In each instance the broken, roughened, agged endothelial surface forms a nidus for the ient and growth of thrombi and a suitable site ne development of the inflammatory reaction to *ococcus viridans*, which flourishes in the blood and boured in the resulting vegetations. The picture of ns of irregular vegetations along the edges of the cusps in bacterial endocarditis is well known. As nplication of the patent ductus, similar clumps of ations develop in the pulmonary artery closely ent to the intima from which they spring and st invariably thickest opposite the mouth of the us (fig. 1). Libman (1920) pointed out that this form ngenital heart disease was particularly prone to a ute bacterial infection.

d from the higher pressure system of the aorta, the us throws into the pulmonary artery a continuous f blood at right angles to the main venous flow. double blood-supply, the rapid mixing of the arterial venous streams, the constantly swirling blood cur- , and the increased pulse pressure within the onary artery, all combine to stretch and injure the l wall. With the passage of time local degenerative ges gradually develop. Deposition of cholesterol, ening of the intima, and the gradual development of chy atheroma in the wall of the artery immediately site the entrance of the ductus are the result of the nuous buffeting to which this portion of the vessel is sed. On the damaged surface the infective process lops (Hamilton and Abbott 1914, Schlaepfer 1926). getations form on the atheromatous plaques and spread along the artery to involve the cusps of the onary valve in a bacterial endocarditis, or the ess may extend in circular fashion round the artery each the mouth of the ductus and, in the most nced cases, involve the intima of the ductus. Emboli ched from the fungating vegetations are shed into pulmonary circuit. Lung infarcts are therefore to be cted. Peripheral infarcts are less common, occur in the disease, and, when massive, suggest extensive lvement of the pulmonary artery, with a spread of the mmatory process up the wall of the ductus even to ortic inlet. *Strep. viridans*, the commonest causal organism, can usually be recovered repeatedly from the blood.

CLINICAL FEATURES

It is remarkable that this infective complication of a distinctive form of congenital heart disease should not be better known. The triad of persisting septicæmia, recurrent pulmonary infarcts, and local signs of a patent ductus readily establishes the diagnosis.

The evidence of septicæmia presents no great difficulty, the swinging temperature, the tachycardia, the progressive weakness, the increasing anæmia, and the discovery of splenic enlargement being as a rule substantiated by a succession of positive blood-cultures.

Experience proves that the gross evidence of lung disease may so overshadow the clinical picture as to obscure the recognition of the underlying cause. Bouts of coughing, with some transitory respiratory distress, patches of pleurisy, minor hæmoptyses, and recurrent attacks of "pneumonia," are manifestations of scattered lung infarcts, seldom so dramatic or overpowering as that denoted by the usual conception of the term "pulmonary embolism." It is characteristic of infective endarteritis of the pulmonary artery that the lung infarcts are small, multiple, and repeated. Recurrent atypical pulmonary signs should direct attention to the heart as a possible source of mischief.

The slight handicap imposed by the patent ductus, the absence of the cruder signs of congenital heart disease —cyanosis and clubbing—and the strict localisation of the distinctive continuous murmur to a small area below the inner end of the left clavicle account for the ease with which evidence of this congenital defect may be overlooked, at least in the earlier stages of the infection. With the passage of time, and particularly in older patients, after weeks or months of fever with increasing anæmia and loss of flesh, the cardiac signs alter in character. They become more obvious. The heart enlarges further to the left, the neck vessels develop a bounding pulse, and the Corrigan pulse quickens and grows more striking. The diastolic pressure falls further. The Gibson murmur becomes louder and booming. As the pulmonary artery dilates, the site of maximum intensity of the murmur is displaced more to the left than in the non-infected case. For these reasons the cardiac manifestations, so important in the establishment of the diagnosis, should seldom pass undetected or uninterpreted. When the distinctive triad is present, the diagnosis is readily established.

For success in treatment it is, however, very desirable to make the diagnosis before exhaustion develops from protracted septicæmia and before lung involvement has taken place. In the presence of a patent ductus, continued fever without some obvious cause should at once arouse suspicions and suggest the desirability of repeated blood-cultures. By this means the condition will be recognised promptly and curative measures adopted even before pulmonary infarcts occur.

A clearer conception of the diagnostic problem may be obtained by the consideration of case 6, selected as representative of the whole series. The course of the illness, the complications, and the problem of adequate care as faced by the doctor in country practice are illuminatingly summarised in the letter with which he referred his patient to hospital and which is quoted below:

Case 6.—A shepherd's wife, aged 27, the mother of three children, arrived in hospital on Sept. 17, 1946, with eight months' history of increasing exhaustion. She looked gravely ill, sallow, drawn, anæmic, wasted, and a little dyspnœic as she lay at rest.

In recommending her for hospital care her doctor wrote as follows: "Mrs. F. has suffered from endocarditis since childhood, but I have only had her under my care since July, when I took over this practice. My predecessor thought she had tuberculosis, as she has been going downhill since the birth of her last baby $7^1/_2$ months ago. She has had evening fever, sweating, loss of weight, and cough; but it has been difficult to make a thorough examination of the chest, because the heart condition made it difficult to hear other sounds properly. She was notified as tuberculous, but the Public Health Department radiographed her and reported that the plate showed only signs of congestion due to the heart. A series of sputum examinations was negative. She has been having rigors recently, and her temperature in the afternoon often goes up to 102°F; so I think she has a bacterial endocarditis and would be glad if you could do something for her, though it can only be a patch up at best, I am afraid."

History.—As a child she received no education, since the school medical officer considered her unfit to attend school. She was then at most a trifle breathless on heavy exertion, insufficient to prevent her entering domestic service at 15 years, and later working on her father's smallholding. She felt fit and well. The work was hard and the hours long. Her only illness of note was diphtheria at 8 years of age.

She married at the age of 21, and had three successful pregnancies and normal deliveries without cardiac distress. Her housework and her children, now aged 5 years, 3 years, and 9 months, have been her entire responsibility and have not overtaxed her strength. She was perfectly well until January, 1946.

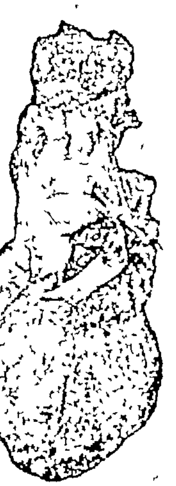

Fig. 1—Infective endarteritis of pulmonary artery (case 3). A marker has been inserted behind ductus, which has shrunken greatly as a result of ligation 3 days before death. Pulmonary artery, opened in its long axis, contains a mass of luxuriant vegetations, most profuse opposite orifice of ductus.

Her third child was born in December, 1945—a normal labour and puerperium. About the end of January, 1946, four upper premolars were extracted by her doctor without simultaneous sulphonamide medication.

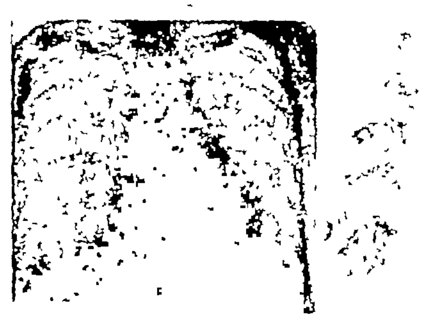
Since that time she had complained of being "tired and done." About June she became weaker and was admitted to the local cottage hospital, where she had a course of sulphonamide and a total of 20 injections of penicillin—actual dosage unknown. She felt temporarily better, but on returning home after a month's care she soon relapsed and had been confined to bed ever since, because of evening fever, sweating, loss of strength, loss of 21 lb. in weight, occasional bouts of coughing, and increasing anæmia.

Examination revealed evidence of septicæmia, her temperature fluctuating between 97° and 104°F and her pulse-rate between 76 and 130. Her respirations ranged from 24 to 48. She weighed 78 lb. (standard weight for her age and height being 129 lb.). Anxious, wasted, and anæmic (Hb 70%), her spirit was excellent and she made light of her distress. Spleen palpable, enlarged by two finger-breadths below costal margin. Five consecutive blood-cultures made during her first three days in hospital were positive. The successive counts were 43, 14, 23, 19, and 14 colonies of *Strep. viridans* per c.cm. of blood. Coefficient of penicillin resistance = 2/3. Erythrocyte-sedimentation rate (E.S.R.) 23–26 mm./hr. White cells 9200–5400 per c.mm.

The most striking signs on physical examination were confined to the circulatory system. Bounding neck vessels, and a Corrigan pulse (blood-pressure 110/50), an enlarged heart (fig. 2), a left basal thrill, and the typical loud booming Gibson murmur maximal in the 2nd left space 2–4 cm. from the midline, with an accentuated second pulmonary sound, justified a diagnosis of a patent ductus. There was no evidence of any other cardiac defect.

No petechiæ about the root of the neck or conjunctivæ, or elsewhere. No splinter hæmorrhages, Osler's nodes, or tender finger-pulps. No clubbing. Urine contained albumin 0·25 g. per litre, a few granular casts, and occasional pus cells. No signs of congestive failure.

Though there was a history of recurrent coughs, examination of the lungs did not reveal signs of infarcts. A little moisture was detected at both bases. Radiography showed a dilated pulmonary artery and engorgement of the lung fields. No infarcts.



(a) (b)

Fig. 2—Size of heart (case 6): (a) before operation; (b) ligation of ductus. Reduction in size affects chiefly "waist" due to shrinkage of pulmonary artery. Transverse diameter is appreciably less, and lung fields are clearer.

Diagnosis.—In spite of the absence of conclusive lung we diagnosed infective endarteritis of the pulmonary with patent ductus arteriosus.

Course of Illness.—Her general condition was so p 9 months of continued septicæmia, her emaciation so and her exhaustion so advanced, that we judged i surgical interference inadvisable. A course of pe 500,000 units daily was begun on Sept. 20 and continued Oct. 20—31 days.

A series of embolic incidents was observed soon after st penicillin: on Sept. 21 a single petechial spot at outer of left conjunctiva; on Sept. 22 a small pulmonary i with pain and friction in left axilla and minor hæm next day; on Sept. 26 bright red blood in stools; on pain in right renal angle and red cells observed in urine first time; on Oct. 5 very severe pain in right side of and shoulder with pulmonary infarct of right lower Weak and exhausted. Critically ill. Temp. 104°F, p 120–130, respirations 30–40 per min.; Hb 50%; 100 mm./hr. Rallied after a blood-transfusion (Oct. 5) 2 pints, which corrected shock and restored Hb to No further infarcts were observed after Oct. 4, the 15th of penicillin treatment, which was continued 4-hourly w interruption until Oct. 20. Ten days after her tran her general condition had so far improved as to ligation. Her temperature had settled, her pulse rate 80–100 per min., the lungs were clear of gross signs, and successive blood-cultures since starting penicillin negative.

Ligation of Ductus (Oct. 15).—Through an antero approach the ductus was found lying far back and over by some large glands. On the posterior aspect adhesions fr than usual made the dissection more than usually diff With the help of cystic-duct forceps a burrow was made close to the aorta as possible. The ductus, almost 1 cm diameter, was doubly ligated with silk ligatures. Immediately after ligation, with a sterile stethoscope placed lightly on pulmonary artery distal to the ductal orifice, a systolic murmur was heard, but not elsewhere. Blood-cultures taken 10 m before ligation, immediately before and after, and $^1/_2$ hr after, were all negative.

Postoperative Course.—The patient was nursed in an oxy tent for the first 24 hours. She rapidly gained strength small effusion collected at the left base, 45 c.cm. of blood stained fluid being aspirated on Oct. 22. Her diastolic pres stabilised between 70 and 80 mm. Hg. She had no furth infarcts.

At the time of her discharge from hospital on Dec. 12 h weight was 102 lb., Hb 90%, E.S.R. 5 mm./hr., and h general condition entirely satisfactory. She had, howev a residual pulmonary diastolic murmur strictly localised t a small area and interpreted as evidence of incompetence the pulmonary valve. Six months later she was in excell health, fit for a full day's work, but the murmur was lo and longer, suggesting incomplete ductal occlusion. diastolic pressure was 70 mm. Hg before and after a vigor exercise test.

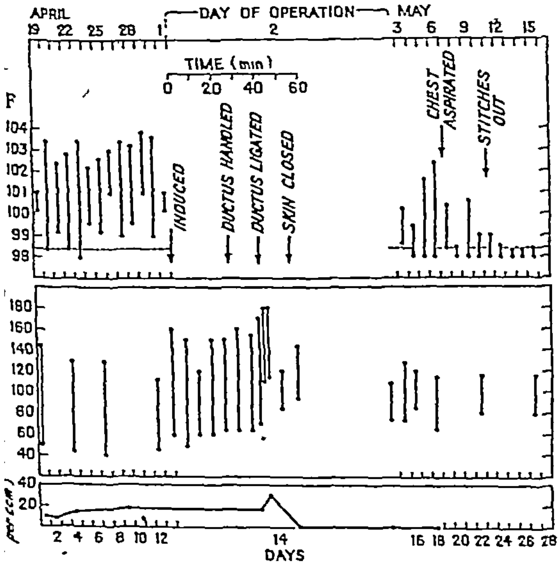
This case emphasises certain features common many of these patients. Worthy of consideration particular are the long period of invalidism before the dia nosis of septicæmia was established, the not uncom n with pulmonary tuberculosis, the failure to e the signs of congenital heart disease with the e process, and finally our decision to postpone interference until an *adequate* course of penicillin n put to the therapeutic test. Admittedly, the t of embolic phenomena, coming immediately nicillin was started, cast a doubt on the wisdom policy, but the patient's remarkable recovery and o a life of full activity justified the postponement ion to the first favourable opportunity.

nvenient comparison of the leading features of cases under consideration is presented in the anying table. There was only 1 male in the series, e youngest patient was aged 6 years.

nosis.—Except in case 5, a respiratory-tract on was the original diagnosis in each instance, onia causing the greatest confusion. Case 3 had than six pulmonary episodes, each characterised e development of local signs of consolidation, n November, 1943, and June, 1944, before the ature of the infection was first recognised. The ce of a patent ductus was detected by the doctor, s relation to the septicæmia and the recurrent s of "pneumonia" was overlooked. Indeed, in e of the series were the physical signs adequately ted and the clinical picture assembled as a distinct

et.—All the patients could mark the onset of their definitely enough, though only in one instance 5) did the disease start with a rigor. Loss of strength, f energy, and fever and sweating, with temperatures 101–102°F, were common in this series even for hs at a time before energetic measures or even -cultures were taken. In a corresponding series of ses of subacute bacterial endocarditis an average d of six weeks elapsed before the patient was tted to hospital. As many months may pass before patient with the infected pulmonary artery reaches ward, perhaps because "pneumonia" appears an uate diagnosis until it has recurred several times.

ripheral emboli are not a striking feature. They obvious only in 2 patients (cases 2 and 6), in both of m the disease had run a long course, 13 and 8 months ectively. In case 3 the presence of an "embolic" nephritis was confirmed at necropsy, but its origin and nature are rendered obscure by the fact that the vegetations were strictly confined to the pulmonary artery (fig. 1). There were no vegetations in the ductus or the aorta. It is difficult to believe that emboli could travel against the main stream through the ductus; therefore the absence of vegetations near the aortic orifice of the ductus supports the view of Bell (1932), who considers that the renal lesion, in bacterial endocarditis, is toxic and not embolic in origin. The success achieved in case 6, who had numerous though small peripheral emboli, indicates the importance of perseverance with penicillin, even in desperate cases, in the hope that surgery may be successfully undertaken.



3—Effect of ligation of ductus on course of septicæmia (case 5). om above downwards chart records maximal and minimal daily mperatures, blood-pressure, and quantitative blood-cultures for days. Day of operation shows closure of ductus is followed by nmediate rise in diastolic pressure from 70 to 110, and by sterilisation blood within 16 min.

Pulmonary emboli are so frequent as to form a distinctive feature. Indeed, when pulmonary infarcts are repeated, the changing pattern of the heart and lungs in successive radiograms throughout the course of the disease may suggest its recognition to the radiologist (Gilchrist 1945). Ideally, the diagnosis of infective endarteritis should be established before the occurrence of pulmonary infarcts, which exhaust the patient, add greatly to the severity of the illness, and at a later date, by preventing collapse of the lung, may interfere with the surgical approach to the ductus. This difficulty was encountered in case 1, a large infarct involving the left lower lobe. The demonstration of a persisting septicæmia, particularly the repeated recovery of *Strep. viridans* from the blood, in the presence of a patent ductus, justifies the diagnosis. For example, case 5 had been ill only nine days when the diagnosis was made on the basis of a succession of positive blood-cultures (*Strep. viridans*) with clinical signs of a patent ductus. She had no pulmonary symptoms or signs and escaped the embarrassment of lung infarcts both before and after surgical ligation. She was not treated with sulphonamides or with penicillin. She has made a complete and lasting recovery.

Causes of Death.—Of the 3 fatal cases, 2 deaths were attributed to massive pulmonary collapse three days after operation in each instance. The third patient (case 2), gravely ill with congestive heart-failure, died without effective treatment.

LIGATION AND CHEMOTHERAPY

Dating from the work of Bourne et al. (1941) and Tubbs (1944, 1946) in this country, Touroff and Vesell (1940) and Touroff (1942a, b, and c, 1943) in America, the tendency has been to emphasise the absolute necessity for prompt closure of the ductus as soon as the diagnosis of infection is established. Touroff (1942a, b, and c) demonstrated that within a few minutes of ligation the blood, which had previously yielded profuse growths of streptococci, became sterile—a fact confirmed by Tubbs (1944) and by the findings in cases 4 and 5 of the present series treated exclusively by surgery. For instance, in case 5 (fig. 3) the blood before operation gave a growth of *Strep. viridans* varying between 8 and 18 colonies per c.cm. With the ligatures in position, 3 min. before the knots were tied, cultures yielded 16 colonies; 3 min. after, 30 colonies; 16 min. after, no growth; 85 min. after, no growth; and four days after, no growth—very remarkable proof of the prompt influence of closure of the ductus on the bacteræmia. Case 4, already briefly reported (Gilchrist 1946), made a dramatic response to ligation (fig. 4), the abrupt subsidence of fever, temporarily interrupted by a pulmonary infarct on the fourth day, and the rapid improvement in her nutrition being striking features of an illness which had lasted six months (fig. 5). Both patients continue to keep in excellent health.

There is therefore no doubt that surgical occlusion is extremely effective. Ligation can sterilise the peripheral blood more quickly and more effectively than can penicillin, probably because the abrupt exclusion of arterial blood from the pulmonary artery provides a venous environment of such low oxygen tension that the streptococcus cannot survive. Boldero and Bedford (1924) offered this explanation for the infrequency of subacute bacterial endocarditis on the right side of the heart. The shrinkage of the pulmonary artery throughout its entire distribution ensures a more effective filter, and the cessation of injury within the main vessel must promote healing (Touroff 1942a).

Shapiro (1947), by collecting *information from surgeons* throughout the world, finds that the mortality after ligation in infected patients has fallen from 50% five years ago to 28% now. Further improvement in results will be brought about chiefly by earlier diagnosis. The shorter the course of the disease, the greater the freedom from pulmonary and peripheral emboli; and the more strictly the vegetations are confined to the pulmonary artery, the greater are the prospects of surgical success.

The recent proof of the remarkable efficacy of a 28-day course of penicillin in the treatment of subacute bacterial endocarditis (Christie 1946) suggests the use of similar methods in pulmonary endarteritis. If the causal *organism recovered from the blood is penicillin-sensitive,* on a theoretical basis it appears desirable to eradicate the blood-stream infection and improve bodily nutrition with penicillin before recommending surgery. Pathological experience indicates that the infective process, originally confined to the pulmonary artery, commonly *spreads to involve the heart valves in a bacterial endocarditis.* Clinically, in the presence of an infected pulmonary artery, it may be difficult, because of the intensity of the local physical signs, to exclude with certainty the added complication of a bacterial endocarditis of one or more of the valves. Surgery can arrest the local endarteritis, but it cannot be expected to cure *when a valve is also involved. The use of penicillin is* justified by its unique ability to heal the valvular lesion, which, unaffected by ligation of the ductus, would otherwise adversely influence the course of the disease.

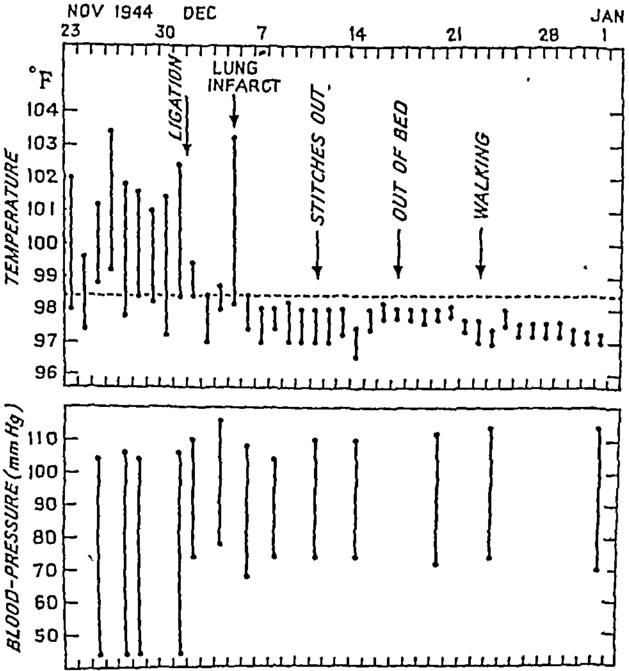


Fig. 4—Effect of ductal ligation on course of fever is shown by change in form of patient's chart, which depicts maximal and minimal daily temperatures and blood-pressure readings. Prompt subsidence of fever, which had persisted 6 months, is temporarily interrupted on fourth day after operation by a single pulmonary infarct. This child (case 4) made a complete recovery. (See also fig. 5.)

The limitations of penicillin therapy must be nised. In the early case there are powerful ar against its preoperative use. To postpone closure of ductus until a penicillin cure is established ex the patient to the continued risks of embolism d the first few weeks of treatment. Even in successful r of subacute bacterial endocarditis peripheral e may occur up to 17 days or more after the start of penicillin course. Serious complications, pulmonary peripheral, may therefore develop during pen therapy. These disadvantages may offset any gain i patient's strength and resistance. Further, the ef of penicillin in the streptococcal complications of various forms of congenital heart disease has not yet fully assessed. The attempted cure of an infected monary artery with penicillin may not prove su and delay may lead to death before or after oper Though the infection may be cured with penicillin patent ductus persists and the endarteritis may r or recur. If penicillin is used with success to combat *the infection and* an interval is allowed to elapse between the end of the course of treatment and *before surgery is* undertaken, the amount of fibrosis will probably increase near the ductus and make dissection more *difficult.* For these reasons it may not be wise to postpone surgery.

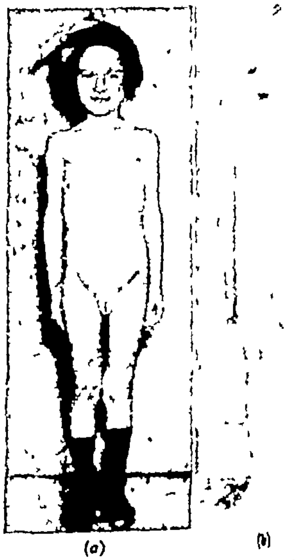

Fig. 5—Bodily nutrition and physical being of case 4; (a) after 6 month refractory to sulphonamides and c ised by recurrent attacks of "p and persisting septicæmia; (b) after ligation of ductus. (See also fig. 4

On the other hand, cases will occur from time to time where the diagnosis has been missed, the infection has in consequence run a protracted course, and the exhaustion of the patient, complicated perhaps in ex instances by respiratory distress and con heart-failure, preclude immediate operation. We faced with this problem in two instances: case 2 too ill for surgery, penicillin was not available. she died a few days later; and case 6, almost recovered with the help of a preoperative course penicillin, though recurrent infarcts in the lung elsewhere during the month of chemotherapy ca anxiety—she stood operation well and made a remark recovery.

It may be concluded that, provided the patie general nutrition is reasonably good, exhaustion toxæmia not extreme, and congestive failure ab closure of the ductus should be undertaken at once implies that, in the treatment of the infected pulmon artery, surgery takes precedence of chemotherapy. full 28-day course of penicillin should be used in more gravely ill patient, judged too weak for sur in the hope of overcoming the infection and com exhaustion. It must be borne in mind that, w penicillin therapy is in progress, there is no satisf criterion of cure (Hunter 1946), and therefore sur ligation, which is more certain in its results, should be long delayed. In gravely ill patients, by comb

ANALYSIS OF CASES

ge ears) nd sex	Original provisional diagnosis	Duration of infection	Peripheral emboli	Congestive heart-failure	Date of operation	Result
9 M	Influenzal pneumonia	$4^{1}/_{2}$ months	None	No	Oct. 12, 1940	Death Oct. 15, 1940; massive pulmonary collapse
2 F	Recurrent pneumonia	13 months	Osler's nodes right foot and forearm	Yes	Not attempted	Death April 17, 1942, 17 days after diagnosis first established
8 F	Recurrent "sulphonamide-refractory pneumonia"	6 months	"Embolic" nephritis	Yes	May 30, 1944	Death June 2, 1944; massive pulmonary collapse
6 F	Recurrent pneumonia	6 months	None	No	Dec. 2, 1944	Complete recovery without penicillin; in perfect health 29 months after ligation
6 F	Acute pericarditis	9 days	None	No	May 2, 1946	Complete recovery without penicillin; in perfect health 12 months after ligation
7 F	(*a*) Phthisis (*b*) Bacterial endocarditis	8 months	1 petechia, "embolic" nephritis, mesenteric infarct	No	Oct. 15, 1946	Complete recovery after full preoperative course of penicillin; residual pulmonary diastolic murmur; in good health 7 months after ligation

herapy with surgery *appropriately undertaken.* success will be attained in the future. It is wise e the ductus as soon as the patient is judged fit d the operation, even before the completion of the course of penicillin.

OPERATIVE TECHNIQUE

s (1939) has recommended the anterior approach through the second left intercostal Because of the greater control of the ductus in hæmorrhage, the wider operative field, and the accessibility, Harrington (1943) has used a lateral incision, but the anterior approach has sed by one of us (W. M.) because of the reduced cy to shock. A flap method is used, the skin n extending from the second right space curving ards below the left breast and up into the left The reflexion of a flap of skin and then a flap of provides later for a valvular type of closure of cond interspace, which is opened up as far as the al mammary artery. The rib above and the rib are divided in front, and access is obtained by etraction.

he older patient the ductus lies further back, as rta gradually assumes a more posterior position. uctus accordingly is found running almost vertically ards in the adult, whereas in younger children its on is more lateral. In infected cases there are y adhesions between the lungs and the mediastinal but it is unusual for these to cause difficulty. they are divided, the mediastinal pleura is palpated e exact site of the ductus located. It usually lies the phrenic nerve, and an incision about 3 in. and parallel with the nerve is made behind it. exposes the area in which the operation will be cted.

eral factors which may give a little trouble have to nsidered. There are often glands in this region, dark, sh, fleshy structures, which often overlie the area which is to be dissected. In the older patient ulmonary artery is often considerably dilated and rs to overlie the ductus. It has to be reflected wards to give a good exposure. A large thymus extending for about $2^{1}/_{2}$ in. from the midline and lly overlying the ductus, recognised by its greyish- appearance and the fact that it seems to lessen ntensity of the murmur when palpated, may be ntered. It is dissected forwards and, in spite of ge size, in neither of the two cases in which it was did it produce any postoperative trouble. When uctus is located by palpation, its junction with the is carefully noted. As recommended by Johnson et al. (1942), *most of the dissection takes place in this* region—i.e., as near its aortic end as possible. In at least one case it was possible to make an incision into the adventitial coat of the aorta, as suggested by Touroff (1942*b*), and burrow under and round the ductus by *closely adhering to the aorta during the dissection.* This manœuvre is not always possible in the older cases through an anterior approach, because of the very posterior location of the ductus.

In the last 3 patients (cases 4, 5, and 6), the technique developed by one of us (W. M.) has been employed. This consists in the use of special cystic-duct forceps. They should have a blunt nose, have no teeth on the end, and have various curves to enable one to burrow at the appropriate angle round the ductus, so that eventually a fully curved pair can be used to place the ligatures in position. They are extraordinarily useful and much safer and less likely to do damage than any of the other methods which have been described. The forceps are insinuated first in the angle between the ductus and the aorta at *the distal attachment of the ductus to the artery.* By gradually pushing them in and opening them it is not difficult gradually to find a way round at this site. After a certain distance has been reached in one direction, a start is made from the more proximal part of the aorta in the opposite direction until the way is clear. In the infected cases this dissection is slow, demanding patience and perseverance, because there is naturally a firmer type of areolar tissue in this region and the ductus is often more adherent to the bronchus behind.

Two pieces of silk are now taken, one being marked with brilliant green at each end to distinguish it from the other. Both are gently drawn round the ductus by the encircling cystic-duct forceps, care being taken not to pull them too quickly or against the ductus. When they are in position they are carefully identified and *tied as close to the aortic end of the ductus as possible.* The knot used is a real surgical knot, not a "granny," and when the surplus lengths are divided they are left rather long. 'Cellophane' as an obliterative agent is unnecessary. *A little sulphonamide* is sprayed into the cavity of the mediastinum. The mediastinal pleura is left open. The chest is now closed in layers and, before the encircling circumcostal ligatures are pulled tight, the anæsthetist *reinflates the lung.* With the flap method of dissection a very good valvular type of closure is obtained without leakage. No drain is inserted.

In no case has the whole length of the ductus been *completely dissected.* Such a procedure increases the difficulties and hazards of the operation and in our opinion is unnecessary. To reduce the liability to recanalisation, which occurred in 8·7% of uninfected ductus after simple ligation (Shapiro 1947), Gross (1944) practises surgical division. When the dissection is confined to the aortic end of the channel, and with the ligatures applied immediately adjacent to the aorta, the procedure is safer and recanalisation unlikely. The most probable cause of this unfortunate complication is the overflow of the ductus walls on either side of the ligature. Fracture of the media by a knot too tightly tied encourages adherence of the overlapping ductus walls and the re-establishment of the channel.

PREVENTION OF INFECTIVE ENDARTERITIS

Infective endarteritis of the pulmonary artery, which is liable to occur at all ages but is less common in childhood, can be prevented by closure of the patent ductus. This is one good reason for recommending that all children in whom this congenital defect is known to persist should undergo surgical ligation, preferably, we believe, between 7 and 10 years of age. Children stand the operation well, and the mortality should be less than 5%.

A second factor in the production of the disease is the development of a streptococcal septicæmia. *Strep. viridans*, an organism of low virulence, is a normal inhabitant of the mouth and commonly gains entrance to the blood-stream as a result of a dental or throat infection. Tooth extractions are a common source of the original bacteræmia (Okell and Elliott 1935, Elliott 1939). By ensuring an adequate sulphonamide content of the blood before oral surgery is undertaken the streptococcus can be rapidly destroyed and septicæmia prevented. All patients with valvular or congenital heart lesions in whom oral surgery is contemplated should be treated before and after operation with full doses of sulphathiazole—doses comparable to those used in lobar pneumonia. The sulphonamide should be begun 8–12 hours before the operation and continued for at least 48 hours thereafter. Penicillin can be used in addition to the sulphonamide if thought necessary. Immediately before dental extractions an injection of 100,000 units, followed by two or three further doses of the same quantity at 4-hour intervals thereafter, may be administered along with oral sulphathiazole in the interests of prevention. There is no doubt that routine prophylactic measures such as these will do much to prevent the development of these serious conditions (Budnitz et al. 1942, Northrop and Crowley 1944). The full coöperation of dental and oral surgeons when handling these cardiac patients will be most welcome.

SUMMARY

A series of 6 consecutive cases of infective endarteritis of the pulmonary artery is described in the hope that increasing familiarity with this serious complication of the patent ductus arteriosus will lead to its earlier recognition. The diagnosis should be made before lung infarcts occur.

Of the 6 patients 3 recovered, including 2 treated exclusively by surgery and 1 with penicillin preparatory to ligation.

In successful treatment surgical closure of the ductus is of outstanding importance and takes precedence of chemotherapy. Penicillin 500,000 units daily for 28 days may be used in the more gravely ill patient judged too exhausted for immediate surgical intervention, in the hope of overcoming the infection and thus preparing the way for ligation of the ductus, but the risks of further pulmonary infarcts in the first few weeks of penicillin therapy are very real. Early ligation should be urged.

The operation is described. The dissection and ligation are facilitated by the use of cystic-duct forceps adapted to this particular purpose. To reduce the tendency to recanalisation the ligatures should be applied to the ductus close to its aortic orifice.

The development of a *Strep. viridans* septicæmia be prevented by the routine use of sulphonamides operations on the mouth and throat. The coö of dental surgeons in the care of patients with and congenital heart disease will reduce the incid bacterial endocarditis and infective endarteritis.

The most effective step in the prevention of endarteritis of the pulmonary artery is to k children known to harbour a patent ductus *observation until the age of 7–10* years, about time surgical ligation should be performed.

In the surgical treatment of the patent ductus we to acknowledge the pioneer work of Sir John Fraser, kindly placed at our disposal his operation notes of and 3 included in the present series.

LOW BACK PAIN

J. D. Paulett
M.R.C.S.
LATE CAPTAIN, R.A.M.C.; MEDICAL REGISTRAR, POSTG
MEDICAL SCHOOL OF LONDON

Cases of low back pain are commonly divided the organic, which are labelled fibrositis, rheum lumbago, &c., and psychogenic (Halliday 1935, Dunbar 1938, Ellerman et al. 1942, Jackson Boland and Corr 1943, Heaton 1944, Flind and 1945, Le Vay 1947). The question of backache investigated at a military general hospital in in 1944, in 25 cases in which no organic was found. The average age of these patients 32·5 years and their average length of Army years, showing that some belonged to the Regular Territorial Army. In 15, transferred from other units, the previous diagnosis was fibrositis in some form of rheumatism in 6. In those de "rheumatism," "arthritis," "myalgia," &c., the sedimentation rate (B.S.R.) was normal, there was fever, and there was no involvement of joints.

CLINICAL PICTURE

A dull ache or an oppressive or tight feeling had been present for years; it was never severe. T were, however, bouts of severe jabbing pain, commonly arose spontaneously but were som precipitated by slight movement such as turning and straightening up after stooping, but this effect of movement was inconstant. Appre often accompanied the pain, especially when it on at night in bed.

There were periodic relapses lasting 2 or 3 weeks the dull ache would be pronounced and the jabs and crippling. During remissions a residuum aching pain could often still be felt, with occ

of the jabbing pain. The average period since
, onset of pain was 3 years 5 months.

vating Factors.—The patients often blamed
, fatigue, and the wearing of equipment as the
f their trouble; but no relief had followed their
xcused the offending duties; on the contrary,
essation or limitation of normal duties their
ity had increased.

veather was often irrationally blamed for causing
avating the illness. Though rain, fog, and damp
leged to have caused rheumatism in the United
m, in Italy sun, dust, and heat were blamed.

was always gradual. Many patients could not
er when their trouble had started. In only
e was the onset sudden and dramatic. It was
r any traumatic or other event to be clearly
ed with the onset.

ological State.—The accompanying table gives
ificant details of each case. Four patients had
ature personality; they were shy mother-fixated
ally adolescent male virgins.

ess, though truly an intellectual rather than a
lity defect, is included here for the sake of

entary schools.

e 25 patients, 20 had an inadequate personality.
who habitually interpret their failures as due to
tances unjustly thrust upon them, may reach a
aranoid state, losing the self-criticism that is
l for social harmony.

commonest signs of anxiety state were tremor,
ve sweating of the hands, and cutaneous or peri-
vasoconstriction. Exaggerated tendon-reflexes,
respiration, casual (non-basal) hypertension,
overacting heart were also noted. In 12 there
oth psychosomatic symptoms and signs; 1 had
igns but no symptoms; and 8 had more than one
m but no signs. Psychosomatic features were
in 21 cases. Of the remainder, 2 patients were
ost profoundly psychopathic personalities in the
The absence of somatic signs and symptoms of
ic tension does not preclude psychological disorder.

ochondriasis was present in 19 cases. Though
ondriasis is common in anxiety states, it was
ronounced and consistent than is usual in anxiety
presenting as such. This is not surprising, since
neurotics had been treated many years for a
ed organic disorder. An attempt to re-educate
long the lines that their symptoms were a bodily
se to fear met with an aggressive reaction which
cted the treatment.

0 there was a history of neurotic traits in childhood;
15 a history of psychological disability in parents,
s, or offspring. In 14 the patients had spent their
ood in industrial slums.

PHYSICAL EXAMINATION

eneral examination was negative, since patients
organic disorders had been excluded from the
As already mentioned, 13 of the 25 had physical
of autonomic disturbance consistent with anxiety
Some showed various degrees of limitation of

ely proportional to the will to flex. There was no
nt muscle spasm, no orthopædic deformity, and
itation of movements involving the sacro-iliac joint.
normal character of muscle texture on palpation
vestigated by examining 50 men who had never
ibrositis. In the rhomboid and scapular regions
ands of tissue were felt, the dimensions of which
be compared with the undulations in corrugated
oard. Fine nodules suggesting surgical emphysema,
oarser nodules of "millet seed" proportions, were commonly found in the trapezius and erector spinæ muscles. The glutæi felt like a flock mattress, some of the lumps being discrete. These nodules, which have been described by Copeman and Ackerman (1944), tended to merge from one variety to another, and were not strictly limited to the sites mentioned as their commonest seat.

In the majority one or several of these variations of muscle texture were discovered, whereas in the rest the muscle appeared to be of uniform consistence. In sparse men anatomical borders of muscles could be palpated as ridges, whereas in the more obese the subcutaneous fat was sometimes lumpy. These effects were not considered significant.

Each patient with low back pain was submitted to an exhaustive examination of all the great muscles of the pectoral, pelvic, and lumbar regions. Attention was paid to tenderness, muscle consistence, and muscle tone, both in the region of the spontaneous pain and elsewhere. The findings are summarised as follows:

(1) Each patient had an area of muscle tenderness close to the spontaneous pain. There were sometimes more than one of these areas which varied in the degree of sharpness of their localisation.

(2) No muscle spasm was found which could not be voluntarily relaxed.

(3) In 8 cases no nodules were found. In 6 cases nodules like those in normal men were found, though none was in the area of muscle tenderness. In 11 cases nodules like those in normal men were found, some of which were in the

tender area; but in all of these similar nodules unrelated to tenderness were found elsewhere, both on the side of the lesion and on the opposite side.

The examination was made with the help of a masseuse who had considerable experience in palpating fibrositic nodules. She was therefore invited to say which cases were fibrositic; these have been marked positive in the final column of the table. The 12 cases she selected differed in no respect from the other 13 and bore no special relationship to any other factor tabulated or described.

It is concluded that any relationship between nodules and muscle tenderness is fortuitous.

BLOOD-SEDIMENTATION RATE

The B.S.R. was normal in all but 2, of whom 1 had an attack of malaria while under observation, the other giving a reading of 13 mm. in 1 hour after a form of therapy known to raise the B.S.R. In the 23 normal readings the average was 6·6 mm. in 1 hour (modified Wintrobe technique) and the range 2–10 mm.

EXPERIMENTAL INVESTIGATION

Induced Pain.—An attempt was made to induce a lumbar pain which would resemble the spontaneous pain in character, severity, and duration (Lewis 1938). It was found that 0·2 c.cm. of a 10% solution of silver nitrate injected intramuscularly into the lumbar muscles produced a pain which lasted 6–8 days. It was of sufficient severity in the first 24–48 hours to prevent vigorous exercise, but did not prevent the patient from walking or sleeping. During the ensuing 24–48 hours the patient was uncomfortable but capable of exercise, such as a game of basket-ball. The pain gradually disappeared in the next 48–72 hours. It was described as continuous and aching; in some cases during the first 48 hours sharp jabs were felt when the patient made certain movements.

Considerable spasm and tenderness were promoted at the site of the injection. For 4 or 5 days painful spasm prevented full movement of the lumbar spine. Tenderness and spasm on palpation persisted a short time after cessation of spontaneous pain and after full movement had returned.

There was some constitutional disturbance as a result of the injection, but this was slight and limited to the first 48 hours. Temperatures did not rise above 101°F. The B.S.R. was temporarily elevated (15–25 mm.).

Ten normal men received these injections. They were patients admitted for some minor organic disorder. Psychological examination showed that they all had normal personalities. The average duration of the three major symptoms and signs were as follows:

Aching pain	5·0 days
Limitation of flexion of lumbar spine ..	4·5 days
Local tenderness and spasm	6·3 days

Concurrently 9 neurotic personalities were given injections. So far as could be judged by interrogation and examination, the neurotics behaved like the normal man:

Aching pain	4·8 days
Limitation of flexion of lumbar spine ..	5·4 days
Local tenderness and spasm	6·4 days

No nodule was ever palpated at the site of the injection. Local spasm and tenderness were the last to disappear. While palpation of the tender area continued to promote muscle spasm, the fingers could learn nothing of the muscle texture, as this examination necessitates complete muscular relaxation. After tenderness and spasm had disappeared, the muscle differed in no way from its uninjected fellow of the opposite side.

Some patients in both groups complained of "jabbing" exacerbations of pain; but it was clear that these
exacerbations were only produced by certain
movements, and that a certain minimal
required. The patients soon learned how to
their movements to avoid giving rise to these e
tions. The "jab" appeared to be the result of
tension in a tender muscle, and its behaviour in the
of this explanation was rational, constant, and p

Conclusions

(1) There exists no demonstrable difference i
tivity to pain arising in muscle between no
neurotic personalities.

(2) Muscle spasm can exist in the lumbar m
normal and of neurotic personalities without
experiencing pain.

failure to help his friends was now quite honourable and
wounded esteem was comforted.

On his recovery from the abreaction no further inq
made into his psychological state, and he was all
believe that it was only the "injury to his back" th
preventing his return to the front line.

Five attempts were made along these lines to
hysterical perpetuation of pain. All the f
including the one described, recovered spontane
with no features to distinguish their behaviour fro
of controls subjected to silver-nitrate injections.

TREATMENT

Physiotherapy.—These patients expect and
physiotherapy. Cures and improvements are fre

lures are numerous (Hurst 1943). In the event of the condition, which has been regarded so long eed of hospital treatment, must now be minimised egarded if the patient is to be discharged. But ould have impressed the patient with the seriousf his disability more than the physiotherapy ment. It is hard for a simple-minded hypoiac to adopt any other attitude than that he has njustly accused of malingering. If he had no logical disability before this event, he would ly have one after it.

ction.—When an attempt is made to remove pain ection of local anæsthetic, success or failure at the f the injection can only be judged by the effect dull aching type of pain; the jabbing pain is constant and unpredictable for profitable study. theless, during the period of relief from aching pain ing an injection patients experienced no jabbing

vas observed that low back pain could be success though usually but temporarily, abolished by the on of local anæsthetic into the area of tender e. It was established further that this could also hieved by injecting normal saline, and even by eedling.

technique used was first to localise by palpation ender area from which the pain appeared to be g. A fine needle, 5 cm. long, was then pushed gh the skin and run in several directions through ubcutaneous tissue. This procedure was painless the needle pricked the skin from below, or the fascia from above. The needle was then witha, and the patient questioned about the effect of injection" on his pain.

the pain was still present, the needle was reintrol, this time piercing the deep fascia and entering uscle. Again the needle was run in several directions withdrawn, and the patient questioned about the on his pain. Should the pain still persist, the le was reintroduced and the tender area of muscle rated with 10 c.cm. of procaine. No effect was uced by running the needle through subcutaneous e.

most cases running the needle through muscle shed the pain. As the needle passed painlessly ugh the muscle the patient would experience a en severe jab of pain, indistinguishable from the taneous type. The needle was pulled back and pushed forward again along the same path, wherethe patient experienced a second jab of pain when needle point reached the depth that had evoked the If this procedure was repeated several times, the cle appeared to grow insensitive to the needle.

here were usually several places in the muscle which ld give rise to pain if needled. The jab of pain so ced was accompanied by reflex spasm of the lumbar cles. But this spasm could be voluntarily relaxed re the induced stab of pain had disappeared. It concluded that the jab of pain was not due to painful m.

those few cases in which this procedure failed to lish pain, infiltration with local anæsthetic also failed.

he operation was performed in a case of referred bar pain from a renal lesion. All manipulation, cutaneous, intramuscular, and local anæsthetic, ravated the pain. The success of intramuscular lling could hardly have been an effect of suggestion, use subcutaneous needling was a consistent failure. urther, the results of this form of therapy did not end on any particular relationship between muscle derness and the nodules described.

t had been noted that pyrexia appeared to re-establish back pain after it had been dormant (Copeman 1943). ravenous T.A.B. was therefore given to reproduce a temporary pyrexia. The subject chosen was a patient cured by intramuscular needling. By alternating artificial pyrexia and therapeutic needling the pain could be made to relapse and remit indefinitely.

PRECORDIAL PAIN OF DA COSTA'S SYNDROME

It will be conceded that inframammary pain of Da Costa's syndrome (Wood 1941) has the same qualities as low back pain. The dull ache, with its oppressive quality, and the spontaneous jabs related to trivial movement are both described. Heaton (1944) observed inframammary pain in 14 out of 26 cases of rheumatic pains unassociated with organic disease.

The behaviour of this pain when subjected to injection is known. It is not affected by local cutaneous or subcutaneous anæsthesia, but is abolished by intramuscular procaine or saline. Several patients with anxiety state and precordial pain were subjected to the same injection as that used in low back pain. Local anæsthetic or simple needling in skin and subcutaneous tissue did not influence the pain. The introduction of the needle into muscle in the region of inframammary tenderness precipitated a jab of pain just like the spontaneous jab. This was followed by abolition of pain. After the procedure had been repeated in 8 consecutive cases with uniform results, it was concluded that inframammary and low back pain behaved similarly both to needling and to injections.

It has also been noted that many patients with Da Costa's syndrome have low back pain also. Of the 25 cases reviewed here 13 also had the inframammary pain of Da Costa's syndrome; indeed, some had originally presented as Da Costa's syndrome and had been previously investigated as such elsewhere. Again, a pain like that of Da Costa's syndrome may be encountered in anxiety states in sites other than the lumbar region.

A gunner, aged 32, with four years' service, had pain in the upper abdomen, on the right side, lasting ten days, with spontaneous remission, in December, 1943.

In May, 1944, a similar attack occurred. He was admitted to 96 General Hospital, where no gastro-intestinal lesion was found.

After three weeks the pain disappeared, and patient was discharged.

In September, 1944, patient had a third attack and was admitted to 22 General Hospital; again no gastro-intestinal lesion was found.

Patient was transferred to 103 General Hospital, where repeated barium radiography, sigmoidoscopy, and examinations of stools did not reveal any lesion.

Patient was referred for psychiatric assessment. He described the pain as a continuous diffuse ache in the upper abdomen, sometimes associated with sudden severe shooting jabs. These exacerbations were apt to come on after meals.

On examination patient was tense and his hands cold, tremulous, and sweaty. In the right upper rectus muscle there was a tender area in which the "shooting" pain originated.

Personality. timid, shy, immature, without adult sexual experiences, and with life handicapped by phobias. He was afraid of darkness, water, and outdoor games. He had had enuresis until the age of 14 years. The subjective symptoms of an anxiety state were also present.

Low back pain and Da Costa's syndrome were diagnosed.

Subcutaneous needling had no effect. On intramuscular needling an exquisitely tender point in the right upper rectus was located, which caused him to experience the shooting jabs of pain. This procedure completely relieved him of his pain.

Ten days later the patient, having had no relapse, was discharged from hospital.

DISCUSSION

The view that low back pain is due to fascial or muscular fibrositic inflammatory lesions is largely based on the existence of so-called fibrositic nodules (Kellgren 1938, Kelly 1945, 1946). The investigations described here tender area; but in all of these similar nodules unrelated to tenderness were found elsewhere, both on the side of the lesion and on the opposite side.

The examination was made with the help of a masseuse who had considerable experience in palpating fibrositic nodules. She was therefore invited to say which cases were fibrositic; these have been marked positive in the final column of the table. The 12 cases she selected differed in no respect from the other 13 and bore no special relationship to any other factor tabulated or described.

It is concluded that any relationship between nodules and muscle tenderness is fortuitous.

BLOOD-SEDIMENTATION RATE

The B.S.R. was normal in all but 2, of whom 1 had an attack of malaria while under observation, the other giving a reading of 13 mm. in 1 hour after a form of therapy known to raise the B.S.R. In the 23 normal readings the average was 6·6 mm. in 1 hour (modified Wintrobe technique) and the range 2–10 mm.

EXPERIMENTAL INVESTIGATION

Induced Pain.—An attempt was made to induce a lumbar pain which would resemble the spontaneous pain in character, severity, and duration (Lewis 1938). It was found that 0·2 c.cm. of a 10% solution of silver nitrate injected intramuscularly into the lumbar muscles produced a pain which lasted 6–8 days. It was of sufficient severity in the first 24–48 hours to prevent vigorous exercise, but did not prevent the patient from walking or sleeping. During the ensuing 24–48 hours the patient was uncomfortable but capable of exercise, such as a game of basket-ball. The pain gradually disappeared in the next 48–72 hours. It was described as continuous and aching; in some cases during the first 48 hours sharp jabs were felt when the patient made certain movements.

Considerable spasm and tenderness were promoted at the site of the injection. For 4 or 5 days painful spasm prevented full movement of the lumbar spine. Tenderness and spasm on palpation persisted a short time after cessation of spontaneous pain and after full movement had returned.

There was some constitutional disturbance as a result of the injection, but this was slight and limited to the first 48 hours. Temperatures did not rise above 101°F. The B.S.R. was temporarily elevated (15–25 mm.).

Ten normal men received these injections. They were patients admitted for some minor organic disorder. Psychological examination showed that they all had normal personalities. The average duration of the three major symptoms and signs were as follows:

Aching pain	5·0 days
Limitation of flexion of lumbar spine ..	4·5 days
Local tenderness and spasm	6·3 days

Concurrently 9 neurotic personalities were given injections. So far as could be judged by interrogation and examination, the neurotics behaved like the normal man:

h eyes swollen, pus welling from palpebral fissures. a of lids, conjunctivitis, subconjunctival hæmorrhages. st full of coarse râles; *urine loaded with albumin.*

atment.—General attention was given to eyes and a, and the patient was given a fluid diet with plenty of e. Atropine gr. $^1/_{100}$ and sulphadiazine 1 g. were given hourly, and penicillin 30,000 units three-hourly.

rse.—At 10.30 P.M. the same day temperature 103·4°F, -rate 126, respirations 36 per min. Chest much drier, he patient appeared more comfortable, sleeping peace- most of the night.

v. 24: extremely restless; heart sounds poor; cough ssing; temperature 102°F, pulse-rate 128, respirations r min. Large bullæ had appeared on face and had burst. on chest had also burst, leaving large denuded areas in. Eyes literally dripping pus, in spite of constant tion by nurses. Restlessness made sedatives (morphine iate gr. $^1/_{20}$, and 'Soneryl' gr. $1^1/_2$) necessary.

sults of Pathological Investigations.—Blood-count: red 5,500,000 per c.mm., Hb 100%, colour-index 0·9; e cells 13,600 per c.mm. (polymorphs 68%, lymphocytes , monocytes 3%). Blood-culture: *B. subtilis* only. sermann reaction negative.

ained films from bullæ showed a moderate number of e cells, mainly lymphocytes; no red cells or organisms . Fluid from bullæ contained red cells and a few nerate leucocytes; no organisms; cultures sterile.

rebrospinal fluid heavily bloodstained, with small clots; rnatant fluid just perceptibly yellow: protein 160 mg. 100 c.cm.; globulin + + +; sugar 0·112 mg. per c.cm.; leucocytes not in excess; no organisms; cultures le; Wassermann reaction negative.

ose and throat swabs negative for Klebs-Löffler bacillus.

ov. 25 and 26: little change in general condition. Fresh e and vesicles appeared and burst, leaving raw areas of rent sizes over face and body. Restlessness could only be rolled by frequent doses of 'Sodium Amytal' gr. $1^1/_2$. perature started to subside, but pulse-rate remained at 116 and respirations 40 per min.

ov. 27: at 5.30 P.M. general condition became worse. patient was cold and cyanosed; temperature 96°F. gical emphysema involving all subcutaneous tissues of k, trunk, and abdomen.

n electric resuscitation cradle was applied and, as it was impossible to get him to take anything by mouth, the ent was given glucose and protein hydrolysate by gastric and retained them satisfactorily. Nevertheless he went dily downhill. It was impossible to register his temperature feel his pulse. Heart sounds became almost inaudible, o was suppressed, and gangrene of right foot was starting.

he patient died on Nov. 30, seven days after admission.

ecropsy.—Body emaciated; epidermis desquamating n lower half of face, ears, and forehead (face looked as if ad been scalded). Numerous discrete and confluent areas desquamation, 1–4 cm. in diameter, on chest over sternum. ddish-brown rash. Larger elements on chest and shoulders were ring-like, about 1 cm. in diameter, some confluent. Centrifugally the elements became smaller, and on the limbs were small brown macules, pleomorphic, mostly polygonal. Blebs containing opaque bloodstained fluid on terminal phalanges of fingers and right heel. No hæmorrhages. No icterus. Subcutaneous emphysema palpable over abdomen. Glands just palpable in both axillæ but not enlarged.

Heart small and rather wasted. Emphysematous bubbles in mediastinum round roots of lungs and pericardium.

Air Passages.—Wall of bronchial tree from larynx to bronchioles lined with yellowish-white membrane, rather like thrush—thin, friable, and easily removed, but too friable to be picked up with forceps. Mucosa deep to it slightly roughened and pink. This membrane was very evident in smaller bronchi and bronchioles, where it was more inspissated and appeared to block most of the smaller bronchi completely. No membrane in pharynx or on vocal cords.

Lungs.—Lower third of both lungs deep purple, airless, and rather dry, with plugs of yellowish material in bronchioles, but no pus. Pleural surfaces showed bright pink slightly raised patches which showed up clearly against bluish-grey background. Upper portions normal, except that air could be moved easily from one part to another. No obvious emphysematous blebs. No free fluid in pleural cavities. Thyroid and thymus glands normal.

Liver normal in size; colour dark, with lighter "dappling" in parts. *Spleen* normal; rather small. *Kidneys* of natural size; pale except for a line of congested vessels between cortex and medulla: capsules stripped easily, leaving a smooth surface. *Suprarenals* showed some blurring at junction of cortex and medulla; rather soft; no hæmorrhages; size normal. *Pancreas, stomach, intestines, bladder* normal. Culture of *heart blood* sterile. *Urine* clear; microscopy showed granular casts and leucocytes in moderate numbers; no red cells; cultures gave *Staph. albus* and *Bact. coli. Brain and meninges* heavy but dry; a little pitting in end surface of basal ganglia; vascular points in the cut surface generally rather prominent.

Lung sections: plugging of bronchioles with fibrinous exudate containing a few leucocytes; very little desquamation; no pus; patches of collapse surrounded by acute emphysema, some being interstitial; no evidence of infection or consolidation.

COMMENTS

This was an extremely puzzling case on admission to hospital. Several experienced physicians saw the case but could not give any clue to the diagnosis until similar cases were reported in THE LANCET. This at least illustrates the importance of publishing unusual cases.

The cause of the subcutaneous emphysema was not demonstrated at necropsy, but the severe cough and restlessness may have been a contributory factor in rupturing a small emphysematous bulla at the hilum of the lung, or causing a small perforation in an already damaged trachea or bronchus.

Neither penicillin nor sulphonamides had the slightest influence on the course of the disease.

I wish to thank Dr. T. Peirson, medical officer of health, Plymouth, for permission to publish the case-note; Dr. W. Lister for his interest in the case; and Dr. M. Thomas for investigating the pathology. It is regretted that permission to publish fuller photographs could not be obtained.

"... Government has become increasingly paternalistic, its actions being based upon the assumptions that the people do not know what is good for them and that, even if they did, they are not in a position to secure it by their own efforts.... And so it is that government has increasingly become concerned with the translation of the discoveries and recommendations of the scientist and technician ... into plans and projects having for their object the provision of an optimal physical and social external world. ... It is not ... enough ... to provide by legislation the means for the satisfaction of human needs ... health and the means for its attainment cannot be forced upon an uninterested community ... they must be taught to want and to value it.

... The very best and best-intentioned measures will be fruitless unless they are welcomed by a population eager to coöperate."—Prof. F. A. E. CREW, F.R.S. (*J. R. sanit. Inst.* 1947, 67, 235).

suggest that nodules palpable in muscle are not necessarily pathological but bear a fortuitous relationship to muscle tenderness in low back pain.

Another view of this pain, especially when it occurs in psychoneurotics, postulates hypersensitivity to painful stimuli (Gordon 1939). The experiments described here revealed no such hypersensitivity. Normal persons and neurotics reacted very similarly to the painful stimulus.

Muscle spasm has been considered to be the cause of pain in this and allied syndromes. Ellerman et al. (1942) state that "the muscle spasm is dependent upon an increase in muscle tension arising from the inhibition of aggression." Elliott (1944), investigating lumbar pain in cases of prolapsed nucleus pulposus, demonstrated with an electromyograph an increased irritability of muscle in the tender areas. The cases described here had no palpable muscle spasm; any spasm provoked by palpation could always be relaxed, even though the patient was experiencing pain.

The muscle spasm of experimentally induced pain behaved in a way clearly distinct from that of the spontaneous pain. Specific movements of minimal vigour constantly aggravated pain associated with muscle spasm. So different were the unpredictable inconstant exacerbations of spontaneous low back pain. Further, in the last 24–48 hours of the induced-pain experiment spasm persisted, though the patient had no pain. Even if muscle spasm can be demonstrated as in Elliott's experiments, it is not safe to conclude that this spasm is causing the pain.

What is certain, however, is that these patients are psychoneurotic, and that their psychological state closely resembles that in Da Costa's syndrome. The pain may occur in the inframammary region, in the low back region, or elsewhere—e.g., in the rectus abdominis muscle. Its pathology is probably the same irrespective of its site.

The pain is not hysterical, imagined, or non-existent. It has simple and clear characteristics. It arises either in, or is closely related to, muscle tissue. It can be abolished with equal success by the intramuscular injection of procaine or of saline, or by dry intramuscular needling. It is not affected by cutaneous anæsthetic. It tends to be remittent, and relapses are precipitated by natural or artificial pyrexia.

There is reason to believe that low back pain, when not due to organic disease, is a psychosomatic manifestation and should be treated as such. The mechanism of low back pain, like that of inframammary pain remains obscure. Nevertheless it appears probable that some local disturbance is responsible, and the discovery of its nature would provide yet another clue to the relationship between psychological disorder and somatic disease.

SUMMARY

An unselected series of 25 cases of low back pain in soldiers without organic disease was investigated. These cases would ordinarily be diagnosed as fibrositis.

The average duration of the disorder was $3^1/_2$ years, indicating that it was chronic or relapsing.

The pain was uniformly described as a dull ache, acutely sharpened from time to time by sudden jabs arising spontaneously or precipitated by trivial movement.

There was abundant evidence of psychoneurosis or of a personality defect in all cases.

It was impossible to establish any relationship between pain and fibrositic nodules. Evidence is presented which suggests that these nodules are innocent variants of normal muscle tissue.

By the artificial production of lasting low back pain with 0·2 c.cm. of a 10% silver-nitrate solution, it was proved that these psychoneurotic subjects with low back pain were not hypersensitive to painful stimuli, that their spontaneous backache was not due to painful muscle spasm, and that it was not perpetu conversion hysteria.

Low back pain may be temporarily abolished by muscular injections of procaine or of saline, or by dry needling, but not by cutaneous or subcu injections or needling. Pyrexia, either natural artificial, caused the pain to relapse.

Low back pain has the same clinical and e characteristics as has the inframammary Da Costa's syndrome, and both occur in the of person. Evidence is presented that these and pains occurring elsewhere in such subjects differ in their sites and represent the same psych manifestation.

Low backache of the kind described should diagnosed as fibrositis, but may conveniently be functional backache.

The mechanism of low back pain remains obscu

I am indebted to Lieut.-Colonel Paul Wood, for his interest in this work, his helpful criticism, revision of the text.

FATAL CASE OF STEVENS-JOHNSON SYNDROME

D. F. JOHNSTONE
M.R.C.S., D.P.H.
MEDICAL SUPERINTENDENT, CITY ISOLATION HOSPITAL
PLYMOUTH

IN the case reported here the illness presented unusual features that, in spite of several other opini it remained undiagnosed until after publication Murray[1] and Nellen[2] of their cases of Stevens-Jo syndrome. It was then realised that this was certainly yet another case of this rather rare di Unfortunately the outcome was fatal, but the r of the necropsy findings may be of interest.

A slim but well-built boy of ten years was admitted City Isolation Hospital, Plymouth, on Nov. 23, 1946, two days' history of general malaise and sore throat. viously he had always been in good health, except for an of measles some years ago. He had been fully imm against diphtheria.

On the day after he first felt unwell he sweated profu felt cold and clammy, and had repeated shivering at His doctor found a blotchy erythematous rash just app on the face and trunk and diagnosed incipient measles.

The patient was put to bed and treated on general but his condition got worse, the rash became more p and he seemed so ill that his parents asked the doct see him again first thing next morning—i.e., three days the onset of his first symptoms. The doctor was so st by the rapid deterioration in his condition that he sent into hospital immediately.

On admission the boy was gravely ill and comatose. perature 104°F, pulse-rate 120, respirations 30 per Severe cough, dyspnœa, and cyanosis of lips. Slightly

ropsy findings.—The brain and stomach only were ied; they showed Wernicke's encephalopathy and oma respectively.

in showed petechiæ in the wall of 3rd ventricle to a of 0·2 cm., corpora mamillaria, grey matter lining n aqueduct, and floor of 4th ventricle as far as lower f pons. Sections showed characteristic symmetrical rrhages with early microglial reaction. Lesions oldest pora mamillaria, where there were plenty of fat and areas of parenchyma loss and vascular hyperplasia.

nach showed diffuse leathery thickening of lower third mach wall, maximal at pylorus, where lumen was icted. Microscopy showed diffuse infiltration of wall undifferentiated spheroidal-cell carcinoma.

DISCUSSION

npbell and Biggart (1939) published an excellent x of Wernicke's encephalopathy. All 3 cases ibed above showed the characteristic focal areas of chyma loss, vascular dilatation and hyperplasia, hæmorrhages and glial reaction, distributed sym- cally throughout the corpora mamillaria and the matter in the walls of the 3rd and 4th ventricles the aqueduct of Sylvius. The hæmorrhages were ly obvious to the naked eye on coronal section of the , but some needed very close inspection, and some only be demonstrated histologically.

e clinical signs of this disease fall into two groups. e of the first group can be explained by the localised ts just described. Thus ocular palsies of every type ommon, and glycosuria, drowsiness, hyperpyrexia, ting, and respiratory disorders have been described.

he second group, more difficult to explain on an omical basis, are mental changes, such as dis- tation in time, confabulation, and mental con- n deepening into coma. The condition may also ssociated with peripheral neuritis.

ie syndrome was first described by Wernicke (1881), 2 out of 3 of his patients and most of those in the equently recorded cases were chronic alcoholics. bürger (1936), however, reported a series in ents with carcinoma and chronic gastritis. Since it has been described in a wide variety of medical surgical conditions, the most common being those ciated with gastritis and vomiting.

vidence is accumulating that Wernicke's disease is iarily due to a deficiency of vitamin B_1. De Wardener Lennox (1947), reviewing 52 cases in prisoners-of- conclude that Wernicke's encephalopathy was ed in those cases solely by acute thiamine deficiency; treatment with thiamine injections produced rapid complete cure. Similar lesions have been produced rimentally in pigeons on a diet deficient in vitamin B_1 xander et al. 1938). According to Alexander (1940) lesion can only be produced in pigeons if other mins are fed. In Chastek paralysis, a disease of s fed on a diet composed of 10% fresh fish, there are ns identical with those found in Wernicke's encephalo- ly, and the disease is curable with vitamin B_1 (Evans l. 1942). Wortis et al. (1942) reported survival in consecutive cases of Wernicke's encephalopathy in after treatment with thiamine. Since the ophthal- legia always responded to thiamine therapy but the ital symptoms often did not, they considered the ase to be a deficiency of several nutritional factors, of which was probably nicotinic acid. Vitamin B_1 s a part in the katabolism of carbohydrates, and t of the symptoms of deficiency only develop if the , contains abundant carbohydrates.

his holds for Wernicke's encephalopathy, and the hanism of development of symptoms is well illustrated he 3 cases described here. Case 1 lived for years on iet deficient in vitamin B_1. This alone might have sed her gastric atony and vomiting. A crisis was hed when her diet became restricted to milk puddings ng to extraction of teeth. Case 2 had access to a diet containing an adequate quantity of vitamin B_1, but she developed pyloric stenosis and habitual vomiting, which brought general starvation. This alone did not cause Wernicke's encephalopathy, but in hospital she was induced to retain a high-carbohydrate diet, whereby coma was precipitated. Case 3 was on a full diet until a carcinoma of the stomach caused vomiting. She also was persuaded to retain her food in hospital, and this was rapidly fatal.

Untreated, this disease is usually rapidly fatal. The ophthalmoplegia is curable with vitamin B_1, but the mental symptoms are very resistant to treatment. It must therefore be emphasised that the condition should not be allowed to develop. Patients with alcoholic gastritis, carcinoma of the stomach, or pyloric stenosis should be given a high-vitamin diet especially rich in vitamin B_1.

SUMMARY

Three cases of Wernicke's encephalopathy are described, illustrating how the condition may arise in surgical cases. Patients with a history of dietary insufficiency or prolonged vomiting should be given vitamin B_1. Otherwise the high-carbohydrate hospital diet may prove fatal.

My thanks are due to the honorary staff of the Sheffield Royal Hospital for their kindness in allowing me access to their cases and reports, to Prof. H. N. Green for help and criticism, and to Mr. D. Bradey for his neurohistological preparations.

PERINEPHRIC ABSCESS TREATED WITH SULPHADIAZINE AND PENICILLIN

J. Shafar
M.D. Glasg., M.R.C.P., D.P.H.
ASSISTANT PHYSICIAN TO OUTPATIENTS, GLASGOW ROYAL INFIRMARY; VISITING PHYSICIAN, LENNOX CASTLE E.M.S. HOSPITAL

J. Garber
M.R C.S.
MEDICAL REGISTRAR, LENNOX CASTLE E.M.S HOSPITAL

We are prompted to present the following case-record because of the cure, reported by Ockuly et al.,[1] of a perinephric abscess with penicillin in a man, aged 30, the subject of recurring attacks of malaria. Four days' treatment with sulphadiazine had not produced any improvement; so continuous intravenous penicillin therapy was adopted, at the rate of 60,000–125,000 units every twenty-four hours for ten days, a total of 925,000 units being administered. The temperature gradually dropped to normal in eight days. Five months later the patient was still free from symptoms. Ockuly and his co-workers state that, so far as they know, this is the first example of this disease which has been treated and cured with penicillin therapy alone. We have not been able to trace any further reported examples.

CASE-RECORD

A man, aged 34, was admitted to Lennox Castle E.M S. Hospital on July 10, 1945, with pain in the right hypo-

WERNICKE'S ENCEPHALOPATHY
IN SURGICAL PRACTICE
REPORT OF THREE CASES

H. J. BARRIE
B.M. Oxfd
PATHOLOGIST, THE ROYAL HOSPITAL, SHEFFIELD

IN 1940, among 5949 medical and surgical inpatients 3 cases of Wernicke's encephalopathy came to necropsy. *This summary of them emphasises that the syndrome* may come within the surgeon's province.

CASE-RECORDS

Case 1.—A married woman, aged 46, was admitted in January, 1940, with the tentative diagnosis of pyloric obstruction, and ten years' history of frequent attacks of abdominal pain immediately after food.

In 1935 she had had a small hæmatemesis. There had been no free HCl in a test-meal. Radiography had shown atonicity of stomach, with delay in emptying, but no organic lesion. After six months' treatment with olive oil and alkaline powders she had remained free from symptoms for the next three and a half years. Her diet had contained very little vegetable, potato, or meat, and consisted mainly of white bread, butter, fried fish, and cheese.

In November, 1939, she had had all her teeth out and had then eaten nothing but milk puddings. After ten days she had had numbness in the legs up to the knees and had started *to vomit after food. Vomit had been copious, not associated* with epigastric pain or nausea. She had become "queer," repetitive, and confused about the time, and had had difficulty in seeing. Legs had become weak and completely numb.

On admission she was semicomatose, unable to give a history, but able to obey simple commands, and had headache and a pain in the base of her back. She was flushed, with dry skin. Respirations rapid and sighing. Blood-pressure 86/54. Bilateral ptosis. Pin-point pupils. Weakness and flaccidity of all limbs. All tendon-reflexes absent. No appreciation of pinprick, vibration, or joint movement over legs up to thigh. Bladder distended. Optic disks not seen. *Lumbar puncture produced clear normal fluid at 180 mm.* pressure.

Urine: faint cloud of albumin, pH 6·3, specific gravity 1·020. The deposit contained a few hyaline and cellular casts and a moderate excess of pus-cells.

Blood: non-protein nitrogen 79 mg. per 100 c.cm., blood-chlorides 363 mg. per 100 c.cm., Hb 75%, red cells 4,200,000 per c.mm., colour-index 0·94, white cells 17,000 per c.mm.

Progress.—She became more and more confused and then comatose. Her temperature rose, over three days, to 103°F, and she died five days after admission.

Necropsy findings.—Atrophy of stomach, purulent cystitis, collapse of lower lobe of right lung, and Wernicke's encephalopathy.

Brain showed slight flattening of convolutions; no pressure cone; numerous red petechiæ in upper half of floor of 4th ventricle, extending round Sylvian aqueduct, and in walls *of 3rd ventricle to a depth of 0·8 cm. as far forward as* anterior commissure; lower halves of corpora mamillaria rather gelatinous and injected. *Stomach* dilated, mucosa atrophic; otherwise no visible organic lesion of alimentary tract.

Histology.—The lesions in the brain were restricted to the grey matter surrounding the 3rd ventricle, aqueduct of Sylvius, and 4th ventricle. The most recent changes were *small pericapillary ring and ball hæmorrhages, most of which* were invaded by microglia. The oldest lesions were little patches up to about 1 mm. in circumference, where the brain substance had been completely replaced by fat *phagocytes and hyperplastic* vessels and surrounded by a zone where microglia and astrocytes were abundant and hypertrophied.

Case 2.—A married woman, aged 63, was admitted with the tentative diagnosis of pyloric *obstruction and a history that* ever since childhood she had been subject to periodic attacks of vomiting, when she brought up all her food. Attacks had developed two or three times a year and lasted from three days to a week. They were not precipitated by emotional though she was of a nervous disposition. Never p For three months she had had what was regarded as a bout of these attacks and had become progressively and more dyspnœic, with the result that for the last ten she had been unable to get up. No pain, paresis, or p thesia. Very restive. No incontinence of urine. headache. Continuous vomiting. She was almost tee her diet was stewed meat, lots of potatoes, margarine, brown bread.

On admission.—Cataract in the left eye; lens of right removed eight years before. She appeared to be n *Skin very dry and lax. Generalised* weakness. All present but weak. Almost complete loss of sensation pinprick and vibration over legs to mid-third of Radiography showed hypertonic stomach with much res fluid, delay in emptying, and deformity in the pyl region.

Progress.—In hospital she retained her food, which co of milk puddings, bread, tripe, and mashed potatoes. two days she suddenly became dull and very forgetful, on the third she was comatose. Temperature 1 pulse-rate 138, with attacks of fibrillation. Well Cheyne-Stokes breathing. Complete flaccidity of all Plantar reflexes absent. Slight papillœdema of right left disk not visible because of cataract. Alkali 66 c.cm. per 100 c.cm. CO_2. Blood-sugar 0·22 g. per 100 Blood: non-protein nitrogen 38 mg. per 100 c.cm. C spinal fluid (C.S.F.) normal.

She improved slightly on treatment with intrav glucose and 'Betaxan.' She had lucid intervals but downhill slowly, developed cystitis, and died ten days admission.

Necropsy findings.—Pyloric ulcer, pyloric stenosis, mortem digestion of œsophagus, bronchopneumonia, c. *and Wernicke's encephalopathy.*

Stomach very dilated; gastric mucosa reddish, thic and covered with excess mucus. Small shallow scar in m of lower wall of pylorus; sphincter thickened with m pearly-grey tissue which took the place of most of the m This and the swollen mucosa occluded the lumen, but stretching with a probe could dilate the lumen up to 0·4 diameter.

Brain showed slight atrophy of convolutions; excess C.S.F.; dura adherent to vault; *deep pink* diffuse injection of white matter; purplish flecks in interventricular septum and corpora mamillaria.

Histology.—Chronic pyloric ulcer with fibrosis of sphincter no evidence of malignancy. Brain showed ring hæmor rhages in grey matter of floor of 4th ventricle, surrounding aqueduct of Sylvius, in corpora mamillaria, and in ependymal region of wall of 3rd ventricle, associated microglial reaction, ranging from stumpy migrating mic to fat phagocytes.

Case 3.—A married woman, aged 66, was admitted with diagnosis of carcinoma of the stomach and pyloric obstruction and six months' history of upper abdominal pain, usually immediately after food, and loss of appetite; vomiting at first *infrequent and later frequent and* copious. She had recognised previous meals in vomit. For three months she had had recurrent attacks of diarrhœa and had lost 1 st. in weight. For a week the vomiting had been incessant and *copious. Eleven years ago she had had* a cholecystectomy. Before her vomiting started she had taken a full and varied diet. She was teetotal.

On admission.—Wasted cheerful woman. Tender in le *hypochondrium.*

Progress.—She retained her food well in hospital. After a day she developed diplopia owing to bilateral external rectus palsy, incomplete on the right side. Slight nystagmus *greater on looking to the right.*

Radiography showed a filling defect in prepyloric region and considerable residue in stomach five hours after meal.

Blood: *non-protein nitrogen 33 mg. per 100* c.cm., white cells 16,000 per c.mm., alkali reserve 56 c.cm. CO_2 per 100 c.cm.

Wernicke's encephalopathy was diagnosed; but, before treatment could be instituted, a severe air-raid caused dispersal of all patients. She was transferred to an outlying hospital, where after two days she became completely disoriented and died in coma.

Preliminary Communication

'MIADONE'

AN ANALGESIC DRUG

IADONE' (*dl*-2-dimethylamino-4 : 4-diphenyl hep- -one hydrochloride) was introduced as an esic during the war in Germany, where it was . 'Höchst 10820' or 'Amidone.' Thorp et al.) found that its analgesic action in rats was about owerful as that of morphine and 7–10 times that thidine. Pharmacological and preliminary clinical tigations have also been reported in America, e the drug has been named 'Dolophine.'

s have compared the analgesic potency of miadone those of morphine and of pethidine in ourselves and student volunteers. Pain has been induced very y by working the muscles of the forearm under tions of complete ischæmia (produced by disten- of a sphygmomanometer cuff applied to the arm pressure of 220 mm. Hg), until a definite aching pain ght or moderate severity is felt in the region of the r muscles. If the contractions are then stopped ischæmia maintained), the pain at first diminishes, after 2–3 min. it begins to rise again, continuing ow steadily until in 10–15 min. it becomes intolerable. experience it becomes possible to distinguish the s of pain quite clearly, and figures can be given over the range from the first development of pain e point of intolerance. From eight to ten stages of lopment are usually distinguishable.

this background of a steadily increasing pain the to be tested is injected intravenously, usually nin. after the end of the period of ischæmic muscular ractions, when the pain is of moderate intensity units on our scale). The drug begins to act either rds the end of the injection (which takes 1–1½) or within a minute of its completion. Central ts, such as light-headedness, giddiness, and dis- ances of vision, appear at the same time as relief of pain, all these actions being proportional e dose.

compare the analgesic potency of miadone, phine, and pethidine, the aim has been to find the dest dose of each which completely relieves moderate (4–5 units). The following approximate equi- gesic doses (the smallest to relieve pain completely) found :

mg. of miadone=7·5 mg. of morphine=75 mg. of idine—i.e., miadone is about as potent as morphine and imes as potent as pethidine.

iadone produces at least as much euphoria as mor- e and pethidine, and therefore must be considered ssible drug of addiction. Other side-effects, such as iness and blurred vision, are less with miadone with pethidine, and observations on 12 other nal subjects suggest that nausea and vomiting are frequent with miadone than with morphine.

e are grateful to Mr. R. M. L. Dry and Mr. J. W. tham for their coöperation as subjects in this work, and Messrs. Burroughs Wellcome & Co. (The Wellcome ndation Ltd.) for supplies of miadone.

Reviews of Books

An Integrated Practice of Medicine

HAROLD THOMAS HYMAN, M.D. Philadelphia and London: W. B. Saunders. 1947. Pp. 4621. Set of 4 vols. £12 10s.

COMPREHENSIVE understanding of the diagnostic and therapeutic problems of the individual patient depends on mastery of the basic doctrines in clinical medicine. There is no other short cut to the integration of specialised knowledge into common medical care. The "compleat physician," we infer, is bred from the marriage of the "science of practice" with the "art of medicine." In this ambitious work of 25 sections, each a textbook in itself devoted to a particular clinical specialty, and written jointly by a general practitioner and a specialist, a complete survey of general medical practice is undertaken, including obstetrics, minor surgery, and laboratory methods. Emphasis has been placed on the patient rather than on his disease, on the beginnings of disease rather than on necropsy findings, and on the coördinated recognition of clinical possibilities. Over 300 tables of differential diagnosis by presenting symptoms and signs punctuate the text; and the index alone forms a separate volume of 300 pages.

Written to meet the requirements of the general practitioner, and reviewing the potentialities of the specialties in any given clinical problem, this work has much to recommend it, but the bounds of general practice are widely conceived: the doctor is expected in his routine physical examination to discover biliary or renal calculi, to include in his diagnostic procedure electrogastrography and the exclusion of causes of "hyponatremia" and "hyperuricemia," and to be capable of performing the operation of paravertebral nerve-block for intractable pain without preliminary practice on the cadaver. But, no doubt to lighten his task, a list has been included of over 200 medical reference books for his library (though these are almost exclusively American), as well as a number of suitable novels for the shelves of his waiting-room. Administrative instruction on the running of his practice does not omit the problems of income-tax, the telephone, and how to deal with impetuous callers.

The general attractiveness of the publication is enhanced by many illustrations. Some of the vividly coloured photographs fail, however, to portray clearly the condition which they represent; examples of skin diseases, often venereal, predominate, and some appear in more than one place in the text. The pictures of vitamin deficiencies, on the other hand, are particularly accurate. Many of the radiograms and the electrocardiograms suffer from reduction.

In an up-to-date and practical work of reference discussion is proper of dicoumarol, thiouracil, folic acid, radioactive phosphorus, and the antibiotics; but the omission is unfortunate of any detailed reference to specific therapy in syphilitic cardiovascular disease, 'Paludrine' in malaria, penicillin in colon diseases, continuous narcosis in anxiety hysteria, and surgery in hypertension and Banti's syndrome. Some useful examples of diets are given for a variety of conditions, from old age to ileocolostomy: and a little ingenuity will transpose the American diets into English equivalents.

The statements that hyperthyroidism cannot be produced by thyroid feeding, that penicillin for bacterial endocarditis is best given by the drip method, and that the X-ray contour of the heart in Lutembacher's syndrome is unaltered, require amendment; while the assertions that gold therapy in tuberculosis should only be used inside an institution and that bile-salts are valueless in the treatment of gall-bladder disease may be questioned. The clinical descriptions of chronic amœbiasis, subarachnoid hæmorrhage, and sciatica are inadequate, and the chapter on neoplasms and the "precanceroses" seems to serve little purpose. But in a work of this size and compass errors are inevitable. On the whole, Dr. Hyman preserves a mature and level balance, and he goes a long way towards achieving his object of demonstrating that the outcome of specialisation is clinical myopia.

chondrium and right lumbar region posteriorly. Eight weeks before admission he had had a furuncle in the neck, which was now healed. The pain was acute, throbbing, and constant, and had been present three weeks. It was uninfluenced by diet, coughing, or deep respiration. The patient also had excessive sweating, but had had no rigors; he had lost a stone in weight since the onset of his illness.

He was well built but pale and anxious and looked ill. Temperature 100°F, pulse-rate 107 per min., and respirations 18 per min. Tenderness and rigidity were elicited over the right side of the abdomen. The lumbar region on the affected side showed a red swelling which felt hotter than the left loin, and the slightest digital pressure over the swelling caused great intensification of his pain. The white-cell count was 14,000 per c.mm.; Hb 65%; blood-sedimentation rate (Westergren) 78 mm. in the first hour, 116 mm. in the second hour; Wassermann reaction negative. The urine contained no chemical or microscopical abnormalities and was sterile on culture. Radiography of the chest and lumbar spine yielded negative results.

Penicillin was started on July 12. Intramuscular injections of 16,000 units were given every three hours for ten days, a total dosage of 1,280,000 units. At the end of this time there was much improvement in his general condition, the pain had decreased, the temperature returned to normal levels, and the pulse-rate was 85 per min. The leucocyte-count had dropped to 10,000 per c.mm., but there was little change in the signs in the right lumbar region.

The patient was then given sulphadiazine by mouth, an initial dose of 2 g. being followed by 1 g. four-hourly, with the usual routine of abundant fluid intake and an alkaline mixture. This therapy was continued for a week. Little change in the patient's condition was noted at the end of this period, and a further course of penicillin of the same dosage as the original was then instituted. The second course extended over six days—a total of 768,000 units of penicillin. Again definite improvement was noted, but the physical signs were unchanged.

During the next few days there was no diminution of the swelling or local tenderness. He was referred for surgical opinion on Aug. 10, and Mr. W. Beattie advised against immediate operation. Subsequent progress was satisfactory, and the swelling gradually subsided and disappeared by the 30th, when the tenderness over the right costophrenic angle had also disappeared.

The patient was discharged at the end of September. He was free from symptoms and had more than regained the original loss in weight. He reported for re-examination on Oct. 28, when his general condition was satisfactory, and there were no clinical signs of his previous illness. Intravenous pyelography revealed no abnormality.

COMMENT

One of the great advantages of penicillin over the sulphonamides is that its action is unimpaired by the presence of pus. Cruickshank[2] has reviewed the place of penicillin in infections of the urinary system. He divides them into two groups. In the first he places staphylococcal infections occurring either as a parenchymatous infection of the kidney secondary to some focus elsewhere in the body or as a staphylococcal cystitis. The organisms responsible for the larger second group of urinary infections—the *coliform group, B. proteus, Ps. pyocyanea, Strep. fæcalis*—are largely resistant to penicillin. We have no proof that free pus was present in the perirenal tissues in our case, but the clinical features seem unmistakable.

The importance of the satisfactory outcome of this conservative treatment is that a condition which formerly required surgical intervention may now respond to chemotherapy alone. Since the perinephric inflammation developed after a furuncle, the infection was probably staphylococcal, and treatment should be continued for several days after apparent clinical recovery in staphylococcal infections because of their tendency to relapse. Such a feature was noted in the present instance, two courses of penicillin (2,048,000 units in all) being necessary before the patient could be said to be cured.

---

MYOMA OF THE SMALL INTESTINE CAUSING INTESTINAL OBSTRUCTION

C. C. Cookson
M.B. Birm., F.R.C.S.
DEPUTY MEDICAL SUPERINTENDENT AND SURGEON, COUNTY HOSPITAL, FARNBOROUGH, KENT

MALIGNANT tumours are generally regarded as a little more common than benign ones in the intestine (Rankin and Newell 1933), and of the tumours the most common is the adenoma, followed by the myoma (Cohn et al. 1939).

Myomata are classified, according to their relatio the intestinal lumen, into inner and outer (Steiner 1898), and the symptoms of the two group quite different. Outer myomata are more li cause intestinal hæmorrhage, the mechanism of is well explained by Smith (1937), whereas inner m usually give rise to intussusception (Rankin and 1933, Fiske 1937). When an outer myoma causes tinal obstruction it usually does so by producing vol

The following case is recorded as an examp a large outer myoma causing obstruction in an way.

A rather frail old lady of 69 was first seen on Jan. when she gave a history of colicky abdominal pa vomiting for three days. For about three years she had constipated, with vague lower abdominal pain, mucus in motions, and moderate loss of weight.

A hard mass was felt in the lower abdomen, rising from pelvis, and rectally this could be felt in the pouch of D where it seemed to be hard and fixed.

Some improvement took place after enemas, b further attack of pain and vomiting, accompanied by a distension, made it necessary to open the abdomen on Ja 1944.

At operation the cæcum and large intestine were mod distended, and the small intestine was of about normal. A firm lobulated mass occupied the whole of the pelvis, which it fitted so closely that it was dislodged with difficulty, though it was not adherent. The mass was at to a loop of lower ileum, which was stretched at this so that its lumen was much wider than normal. The tu was removed with a short section of the anti-mes border of the intestine, after division of a single co adhesion. The bowel at this point being much wider t normal, it was easily reconstructed without narrowing.

Postoperatively the course was smooth; and, when 16 months later, the patient, now aged 71, said that she better than she had done for some years, and had ga weight. There was no sign of recurrence.

The histological report, for which I am indebted to Dr. Gartside, leaves no doubt that the tumour was an inn myoma. The section shows some areas of necrosis and formation, which, however, had no connexion with the of the bowel. There was no evidence of malignancy.

COMMENT

The interest in this case lies in the size of the tu which unfortunately was not weighed but occ practically the whole of the pelvis, and the unusual in which it caused intestinal obstruction. There ca no doubt that it had compressed the pelvic colon at brim of the pelvis.

Preoperatively it had been regarded as an ext carcinoma of the colon, and the case illustrates a p sible disadvantage of performing a blind cæcostomy colostomy in these circumstances.

I am indebted to Dr. J. F. Hackwood for his k comments and his permission to publish this case.

When calcium reserves are depleted

Restoration of correct metabolism can be effected by the administration of Calcydic. The pleasantly flavoured Tablets and Granules contain calcium and phosphorus together with vitamin D, in carefully balanced proportions.

Calcydic is indicated in all conditions in which there is a deficiency of calcium, and when it is anticipated that extra demands will be made on the calcium reserves.

Calcydic Granules contain calcium mono-acid phosphate 12.5 per cent., dextrose 60 per cent., and vitamin D, 40,000 i.u. per 100 g., and are available in tins of 8 oz. and 16 oz.

Calcydic Tablets contain 20 grs. of the granules and are available in bottles of 40 and 100 tablets.

Skin Diseases, Nutrition, and Metabolism

ERICH URBACH, M.D., F.A.C.A., associate in dermatology, University of Pennsylvania; with the collaboration of EDWARD B. LE WINN, M.D., F.A.C.P., associate in medicine, Jewish Hospital, Philadelphia. London: W. Heinemann. *1946. Pp. 634. 50s.*

THIS book is sure to be widely read, and can be recommended for study even in countries where, if a diet of any complexity is prescribed, there is little hope of the patient being able to buy the ingredients. In reading it, however, the postgraduate student should keep a sense of perspective: other authorities are less impressed than Dr. Urbach with dietetic and metabolic theories of ætiology. For example, while a few cases of circumgenital and axillary dermatitis may be due to intestinal putrefactive dyspepsia, there are (as he is careful to emphasise) many other causes of eruptions in these delicate areas.

The book has a large scope, dealing with the influence of nutrition on the physiology of the skin, nutritional causes of dermatoses, the influence of diseases of the liver, pancreas, and intestinal tract on the skin, and the nutritional therapy of skin diseases. The sections on cutaneous glycohistechia, malnutrition (including vitamin deficiencies), *allergic reactions to food*, seborrhœic dermatitis, psoriasis, and neurodermatitis deserve special attention. Dr. Urbach and his colleague have avoided the pitfall of stating that because, in 8 out of 10 cases of some rare disease, von Reckless found low initial levels of vitamin x in the blood, and because the malady gradually responded to the oral administration of a billion units daily of the vitamin, the disease was therefore a manifestation of "avitaminosis x." On the contrary, in almost every case they have been careful to emphasise important corollary details.

The chapter on cutaneous tuberculosis deals chiefly with the Gerson and Sauerbruch-Herrmannsdorfer diets, and the outstanding recent work on treatment by vitamin D_2 is only noted in two paragraphs at the end of the chapter. This, however, is the only important defect in a valuable work of reference.

The Management of Fractures, Dislocations, and Sprains

(4th ed.) JOHN ALBERT KEY, M.D., clinical professor of orthopedic surgery, Washington University; H. EARLE CONWELL, M.D., F.A.C.S., orthopedic surgeon to Tennessee Coal, Iron and Railroad Company. London: H. Kimpton. 1946. Pp. 1322. 63s.

IF only for the fine monograph on spinal fractures, this book is needed by all traumatic surgeons. Sections on fractures of the skull by Fincher, and of the face and jaw by Barrett Brown, supplement the chapters by Key and Conwell. The work is large in scope, and lays emphasis on methods found acceptable by the authors; but where these differ from common methods the text declares it. Conservative British methods are described in this American work, just as the more radical American methods which we have absorbed into practice are now given in our textbooks. Study of end-results has at last shown the way to sound standard methods for almost every fracture. The book is well produced, though some of the X-ray photographs are indistinct and unworthy of the text.

Genetics

EDGAR ALTENBURG. New York: H. Holt. London: Constable. 1947. Pp. 452. *16s.*

Altenburg's textbook contains much useful information, and—compared with other books on genetics—very few factual mistakes. Its weakness lies in his unequal way of presenting the material. Some parts, such as the chapter on abnormal chromosome rearrangement, seem to be written for fairly advanced specialists, and would have gained by the inclusion of a few references; others, like that on vertebrate hormones, barely reach high-school standards. The author's conscious attempt to lay emphasis on modern genetics, and "to make the student feel that genetics is a growing science and that important developments are now taking place," has not been very successful, since numerous omissions mar the value of the work: chemical mutation is dealt with in ten lines and Hadorn's important results are not mentioned at all; nucleic acid is not in the index; pleiotropism is not discussed in real examples, but only superficially and in a general way; and genetics of fungi and bacteria are not mentioned at all, nor are sterility mechanisms in plants. There are many other such examples.

On the positive side, a good and thorough discussion of higher chromosome mechanics forms the bulk of the book. *Of those the author acquired first-hand* knowledge while occupying a laboratory desk in the former "drosophila room" at Columbia University between 1911 and 1913. The book is thus a useful introduction for the student interested in chromosome theory; genetico-developmental problems are treated adequately, and the discussion of genic balance is informative and clear. Human genetics are dealt with rather cursorily, and hereditary diseases and defects in man and other mammals hardly touched on. Hæmophilia, chorea, and the rhesus factor do not occur in the text, and no mention is made of any actuarial or statistical methods in dealing with human material, such as the determination of gene-frequency and consanguinity rates in human populations. The efficiency of twin comparison seems to be somewhat overrated, but the methods employed are sufficiently described. Recent work of non-American origin has been largely neglected, and this is probably the main reason for the book's failure as a general introduction to modern genetics.

Law Relating to Hospitals (London: H. K. Lewis. 1947. Pp. 400. *22s. 6d.*).—The law relating to hospitals straggles over a very wide field, but *it falls* roughly under four headings: constitution and management of hospitals and the administration of their funds; relations with and of the members of the staff inter se; relations with patients; and relations with third parties as in contracts *for supplies and services.* Mr. S. R. Speller, who is not only a barrister but also secretary of the Institute of Hospital *Administrators, addresses his book primarily* to the staffs of hospital administration, but the subject matter of the second and third headings is of equal importance to hospital *doctors. He sets out to cover the* whole of a wide field, and succeeds in doing so simply, clearly, and adequately.

Science Advances (London: Allen and Unwin. 1947. Pp. 253. *10s. 6d.*).—These are reprints of essays by Professor J. B. S. Haldane, F.R.S., which appeared mainly in the *Daily Worker* in the earlier years of the war. (The preface is dated 1944.) They were worth reprinting, though the price of the book will render them unavailable to most of the people to whom they were originally addressed. It is a book to be read, for however much Professor Haldane's habit of tagging Marxism on to scientific discovery may irritate and annoy the orthodox, *these essays tell the interested and avid adult*, who is not a specialist, just what is going on in the world of science. Simply and pleasantly written, covering a wide range of subjects from biography to Nazi "science," and showing an encyclopædic knowledge and a capacity to "put it across," they make a useful and entertaining book.

The National Health Service Act, 1946 (Eyre and Spottiswoode. *1947. Pp. 146. 9s. 6d.).—Between the* covers of this book has been bound a complete copy of the text of the National Health Service Act, 1946, together with an introductory explanation of the Act written by Dr. J. A. Scott and an index to the Act specially compiled by Mr. H. A. C. *Sturgess. It is thus a useful reference book for* all who will be affected by the Act in the months ahead. Dr. Scott, *having reviewed the developing background of* social progress beginning from the time of the Beveridge Committee, takes us through the Act section by section, and from his extensive knowledge of medical administration analyses the effects the Act will have on medical practice as we have known it. His explanations are lucid and comprehensive, and his footnotes make reference to the appropriate section of the Act easy and rewarding. This is particularly true of the sections which deal with services provided by local authorities. The index conveniently refers, not to the sections and subsections of the Act, but to the page numbers of the official copy.

THE LANCET

LONDON: SATURDAY, AUGUST 23, 1947

Management of Poliomyelitis

OST of us have poliomyelitis without knowing it ; is, we become immunised by being exposed to virus without developing any symptoms of the ase. A few have symptoms of a general infection ; fewer still suffer in addition from symptoms neningitis, but never develop paralysis ; fewest ll become paralysed. In an epidemic of poliolitis, therefore, it is necessary to look with ,icion on a child or young adult who for no overable reason has an acute febrile illness, aps with mild symptoms of upper respiratory rrh. Such patients should be isolated from chil- ı and treated expectantly, and the medical er of health should be consulted. They should be t under observation for a week after the temperature to normal, since in poliomyelitis it is common for temperature to fall to normal after 48 hours and ı to rise again with the onset of meningeal and-alytic symptoms two or three days later. They uld be examined daily for the symptoms described ow. If none beyond those of a general infection present it is impossible to prove that the illness been poliomyelitis, though it may have been, and it mpracticable to quarantine a patient for three ks on suspicion alone.

Next in severity come the "meningitic" cases. er two or three days of malaise and fever, sometes interrupted by a remission, the patient comins of pain in the back and headache. There is ally some cervical rigidity ; but more characteristic pinal rigidity which can be demonstrated in a child asking it to try and kiss its knee, which it will be ible to do owing to stiffness and pain in the back. ere will be no paralysis or change in the reflexes. mbar puncture should always be carried out when patient is seen at this stage, not only to confirm diagnosis but to distinguish poliomyelitis from ier forms of meningitis. In poliomyelitis there will a mixed pleocytosis of polymorphonuclear and nonuclear cells, usually between 50 and 150 per ım., a moderate rise in protein, and (in contrast to erculous meningitis) a normal chloride content—)-to 750 mg. per 100 ml. The diagnosis having en made, treatment is still mainly expectant. ough individuals hold different views, such as those t forward in our correspondence columns this week, is generally agreed that neither at this nor at any ier stage is chemotherapy—whether with sulphonides or penicillin—or serotherapy of any use. ialgesics will be needed, and a careful watch must kept for the onset of paralysis.

This may occur at any time between 12 and 72 urs after the onset of meningeal symptoms. Pain d tenderness in the limb muscles are as a rule the st sign that the disease is assuming the paralytic rm, and weakness gradually develops, usually nultaneously in several muscle groups, reaching its aximum in about 48 hours. The affected muscles become flaccid and their tendon reflexes disappear. In the average case the limbs and trunk are alone affected, and the respiratory muscles and bulbar muscles escape. Since the chief danger to life lies in respiratory paralysis, movements of the chest wall and diaphragm must be tested whenever the patient is examined, the latter by asking him to blow out his abdomen while taking a deep breath. Respiratory paralysis may develop in three ways : (1) at the same time as paralysis of the trunk and limbs, (2) as a sequel to an ascending paralysis creeping upwards from the lower limbs, or (3) as a symptom of the bulbar form of the disease. Respiratory paralysis will call for artificial respiration, and as soon as poliomyelitis is diagnosed the doctor should ask himself where the nearest respirator is in case it should be required. The location of these in London is known to the Emergency Bed Service (Tel.: Monarch 8515) and elsewhere to the local medical officer of health.

Though the paralysis usually reaches its maximum within 48 hours of its onset, it occasionally continues to extend. When the worst is known it can be confidently stated that much improvement will take place, but only time will show how much. The object of treatment at this stage is to prevent stretching of paralysed muscles and contractures in their antagonists, and to promote recovery of power. As long as pain persists in the muscles little can be done towards these ends beyond such simple measures as preventing foot-drop by means of a sandbag and taking the weight of the bedclothes with a cradle. As soon as pain is gone and the state of the muscles can be accurately assessed splints and plaster must be called in aid—under the guidance, if necessary, of the orthopædic surgeon—and the physiotherapy appropriate to the chronic stage commenced. Retention of urine may call for catheterisation for a day or two during the acute stage.

Poliomyelitis of the bulbar type may be mild or severe. Unilateral facial palsy or isolated palatal paralysis may be the only sign. On the other hand there may be widespread paralysis of the muscles of articulation and deglutition, with interference with the medullary cardiovascular and respiratory centres. Such patients tax the resources of doctor and nurse to the uttermost. They may need to be nursed in a respirator and fed by nasal tube. Suction may be called for to remove the secretions which otherwise tend to accumulate in the pharynx, and tracheotomy if the adductors of the vocal cords are paralysed. Despite every attention death may follow from medullary paralysis. In such cases artificial respiration may be of no avail, whereas when respiratory paralysis occurs at the level of the spinal cord it may be life-saving by tiding the patient over the crisis until some respiratory muscles begin to recover.

It seems probable that poliomyelitis is still spread mainly by droplet infection, but the virus is certainly present also in the stools and in sewage and may be carried by flies. Nursing, therefore, calls for "typhoid precautions." Nevertheless it is still true that case-to-case infection is rare. It is unusual for further cases to be seen in a household which already has one member affected, even when children have been exposed to the infection. Such contacts may, however, be carriers, and children should be isolated for three

minor deficiencies

B₁ . . . C . . . nicotinic acid

. . . . *but major problems*

Gross deficiency of the primary water-soluble vitamins is rare in this country; but *sub-acute* deficiency states are seen almost daily in general practice. Loss of appetite, insomnia and vague headache are perhaps the most common clinical symptoms associated with a lack of these vitamins . . . and all are indicative of irritable fatigue. To combat either specific or combined deficiency of vitamins B_1, C and nicotinic acid, Glaxo Laboratories present a comprehensive range of preparations . . .

'Berin' *Brand* **aneurine hydrochloride.** By injection when deficiency symptoms are acute; and in gastric atony with gastritis. Orally (3 to 6 mg. daily) when given as a dietary supplement.

Tablets—1 mg. and 3 mg. Ampoules—5 mg. per cc. Ampoules Forte—25 mg. per cc.

'Celin' *Brand* **ascorbic acid.** Specific in scurvy and sub-scorbutic states. Supplements restricted diets and ensures normal vitamin C nutrition during most illnesses and in pregnancy, lactation and childhood.

Tablets—50 mg. Ampoules—100 mg. per cc.

Also available—*Infant* 'Celin' Tablets (10 mg.)

'Pelonin' *Brand* **nicotinic acid.** Indicated in the glossitis, stomatitis, diarrhœa, skin lesions and mental depression of pellagra and sub-clinical pellagra; nutritional psychoses, alcoholic poisoning, Vincent's disease and certain vasospastic conditions.

Tablets—50 mg. Ampoules—50 mg. per 2 cc.

Also available—'Pelonin' Amide (Nicotinamide)—in same strengths.

Combining the three vitamins

NICORBIN. Vitamins B_1, C and nicotinic acid in one tablet. Administered whenever there is evidence of *mixed* deficiency: especially in conditions associated with the alimentary tract; anorexia, stomatitis, fatigue states and general debility.

Dosage of one to three tablets daily normally ensures adequate intake of the vitamins although larger doses may be given when necessary.

Tablets—aneurine hydrochloride 1 mg., ascorbic acid 25 mg., nicotinic acid 10 mg.

GLAXO

Glaxo Laboratories Ltd.,

Greenford, Middlesex BYRon 3434

l. The clinical features of the cases admitted to lare's Hospital are summarised by DEENY and RIEN[2] *in tables which show that the disease* ars suddenly, often in underweight and anæmic lren; the stools are offensive, fluid, and usually green; the temperature is seldom raised except inally. In the newborn, vomiting as well as hœa may be observed. Generally speaking, the is more ill than the clinical findings might est. At post-mortem is found a petechial hæmor- ic condition of the gastric mucosa with minute s. Similar conditions prevail in the small bowel, icularly the ileum, while the presence of abnormal unts of mucus suggests a catarrhal state in the o-intestinal tract as a whole. Enteritis in lin, then, though it has its individual charac- tics, is essentially a particular form of what RGE NEWMAN described as "a general disease of ecific character within wide variations."

the classical epidemics of infantile diarrhœa er in the century the disease was particularly alent in the poor-class districts of the larger is, and the same feature appears in its epidemio- in Eire today. Dublin and the thirteen larger is, with a total population of 800,000, account nore than 60% of the cases, the other 40% arising ng the remaining *2,100,000* people in the country; in the large towns themselves the incidence is istently higher in certain dispensary districts. raised incidence seems to be related to over- ding but not to bad sanitation, and the seasonal t so evident in the classical epidemic is lacking. vever, a clear social gradient is seen in the con- ration of cases in the poorer sections of the munity, with relative immunity of the professional ses Another striking feature is the age-distri- on of cases during the epidemic phase: from a l of 13·0% in the endemic period, which ended in), the percentage of neonatal deaths among the l infant deaths from enteritis rose to 19·1 in the emic phase of the next five years. But the most ing fact of all is the observation that the disease almost limited to children who were artificially

omparing the Irish experience with that of other tries, we see that in Glasgow in 1944 there was arp epidemic of infantile enteritis among infants er a year old which was almost classical in its onal distribution and its prevalence among the nitary overcrowded houses of the poorer quarters he city. Of 522 cases, the child was breast-fed in 22 In Edinburgh in 1942, on the other hand, the t recent form of outbreak, attacking the newborn ifically in certain maternity hospitals, was erved In the United States in 1934 this form ame widespread in hospitals throughout the ntry. A pre-existing nursery infection such as ish or impetigo seemed to set the stage for an break of a fulminating type of intestinal intoxi- on which spread irregularly from cot to cot. parisons between breast-fed and artificially fed dren were invalidated by the universal practice of plementary feeding; but clinically and patho- cally the condition was similar to the type of ess seen in Dublin, and bacteriological investigation proved equally fruitless. The seasonal swing so characteristic of the former epidemics is absent, and *the disease tends to remain localised in specific* hospitals. Recent English experience of hospital outbreaks has followed this pattern fairly closely; though, in Greater London particularly, mortality is unduly heavy among infants over three months old[3]

While therefore more than one type of outbreak can be differentiated epidemiologically, the clinical and pathological findings differ only in degree, and the two main types of outbreak may be present together, as in Dublin, either in endemic or epidemic form. The general nature of the disease has changed somewhat in recent years; meteorological, seasonal, and sanitary factors seem to be rather less important, while convulsions are now seldom seen. Yet DEENY is convinced of the essential unity of the modern types with one another and with the classical epidemics of enteritis in the last century.

On the practical side he makes three main recommendations, concerning milk-supplies, epidemiological control, and isolation Efforts must be concentrated, he says, on the encouragement of breast-feeding among the poorer people in districts which his survey has shown to be specially prone to outbreaks of this very infectious disease An educational drive among parents and doctors is needed to ensure the prompt recognition and notification of enteritis, and measures for isolation—whether by architectural design of clinics and hospitals or by excellence of nursing technique—must be enforced. All this may possibly seem platitudinous; but the continued loss of 500 infant lives each year in Dublin illustrates how far practice falls short of precept. DEENY's preliminary study, though necessarily incomplete, demonstrates the importance of such epidemiological features as changing age-incidence, association with other diseases, time sequences of outbreaks, and the domestic circumstances which favour breast-feeding. If we on this side are to profit by Irish experience, bacteriological studies must be correlated with carefully controlled field surveys.

Swords into Ploughshares

OF late years science has been associated in the public mind with destruction; and the programme of the first full post-war meeting of the British Association, to be held at Dundee from Aug 27 to Sept. 3, has been designed to indicate how science may contribute to human progress. *No doubt* Sir HENRY DALE, F.R S, will point the contrast of these opposing purposes in his presidential address on Science in War and Peace. Subjects of general interest will be considered at the meeting; but there will also be some more specialised contributions In the section of physiology, for example, Prof. WINIFRED CULLIS will deliver her presidential address on Physiology and the Community; while other topics to be discussed range from antibiotics to aviation physiology, climate and health, tracer elements, and man and the machine. The section of psychology is to consider a number of topical questions, including selection for management, public-opinion surveys, and incentives in industry.

weeks after their last association with the patient, who should himself be isolated for three weeks after the onset of his symptoms. Finally, poliomyelitis is a notifiable disease.

Agene and Canine Hysteria

ACCEPTABILITY of bread as an article of food is largely increased by the use of an "improver," a substance which enables the yeast added to the flour to exercise its full value. The one in most extensive use in this country, in America, and in Western Europe is nitrogen trichloride: known commercially as "agene," this has been by far the most popular improver during the past quarter of a century. In everyday milling technique a quantity of NCl_3, somewhere between 3 and 8 mg., is used in the treatment of a sack (280 lb.) of flour, the actual amount varying with the degree of extraction—the higher the percentage extraction the greater the amount of agene employed.

Sir EDWARD MELLANBY[1] has lately published the results of experiments which show that "canine hysteria" can be produced by feeding dogs on agenised flour, *using the amounts of agene which are current in milling practice.* In these feeding experiments the syndrome which goes by the name of canine hysteria appeared after 14–28 days. Dr. MORAN, working at the Cereals Research Station of the Milling Industry at St. Albans, has now taken research in this field a long step forward. In a paper which we publish this week he shows that the symptoms of canine hysteria can be produced in as short a time as 24 hours if the content of agene in the animal's food be greatly increased. An even more important addition to our knowledge is his discovery that it is in association with the protein fraction of flour that the toxic factor leading to the pathological nerve effects is produced. He was able to exonerate the carbohydrate and the fat from any such association, and he was also able to get the same effects by using the proteins of milk and of maize and even by using gelatin. The particular part of the protein structure immediately concerned is left in doubt. Clearly, the condition is not a "deficiency" disease.

No such symptoms, nor others like them, have, so far, been recorded as occurring in animals other than dogs, which thus appear to have a special susceptibility to agenised protein. Nevertheless, it is pertinent to ask what steps, if any, should be taken, whether at the level of technology or of administration, as the result of these investigations of MELLANBY and of MORAN. At first blush it might be suggested that the use of agene as an improver in milling technique should be stopped, and it is true that there are possible substitutes. But a fuller consideration tends to discount any precipitate action. As already stated, agene has been very extensively used for over twenty-five years in the preparation of flour for baking. No toxic symptoms in man, traceable to agenised bread, have ever been recognised, and the dog must be peculiarly susceptible to the particular toxic agent here concerned. Agene is an easily controllable improver and should not be lightly discarded; such discard would probably open the door to a number of alternatives which are by no means easily subjected to scrutiny and concerning which experience is largely l At the moment, while recognising these observat we do not think the position calls for action think rather that the whole subject should re in the field of investigation, with the double ap by medical research and by industry. Some may be created by irresponsible people in the p mind—a thing not easily avoided. But panic those who guide the policy of a great industry, still more among those who safeguard the co health, would be out of place and inexcusable.

Epidemiology of Infantile Enteritis

THE continuing downward trend of mo among infants and children in the last decade made for complacency about infantile en Latterly it has no longer been the serious mena child life that it was at the beginning of the ce Nevertheless various sharp outbreaks in mate hospitals have brought a reminder of the potentialities of this disease. Unfortunately, t bacteriological investigation of such outbreaks incriminated a long list of organisms and their t *their multiplicity implies failure to answer* ætiological problem; so there is something to said for returning to the classical type of inq in which practical indications, like those obtained SNOW on cholera, may be derived from considering disease in the mass. Such a study of the beha and conditions of spread of infantile enteritis reported by Dr. JAMES DEENY,[1] chief medical o of the Eire health ministry.

In Eire there has lately been an ominous rise mortality from this disease, which has been causing annual average of 500 deaths in Dublin alone. This is not part of a general deterioration; indeed the standards of public health in Eire have been refl in lowered death-rates from other causes: and seeking an explanation DEENY has made a serie comparisons of the epidemiological features of *disease both in Eire and in other countries.* show that in the latter part of the last century and the beginning of this, the infantile death-rate enteritis was roughly four times as high in Englan and Wales as in Ireland; but the curves describ the epidemic waves in both countries were ve similar, both in their broad trends over seve decades and in their biennial fluctuations. The 1924 the two death-rate curves crossed and dive *sharply: in Eire the enteritis mortality* has be rising steadily, whereas in England and Wales, un 1939, the trend was just as steadily downwards. the period 1935–41, when the disease was "endemic in Eire, 500–600 deaths occurred each year, but 1941 the present epidemic period began with a dea roll of 805, rising to a peak of 1176 deaths in 19 and causing more than 1000 deaths in every sub quent year. In 1943 the minister of local governme and public health set up a committee of investigatio infantile diarrhœa and enteritis was made a notifiab disease, and research-workers were appointed t examine its bacteriological, clinical, and medic social aspects. The bacteriological studies sho that there was no common agent; indeed in 40–5 of the cases no pathogenic organisms were discove ty or more new types imported with American d egg. Some American authorities are inclined to ot the potential danger from dried egg, and there is scepticism in this country about these "new-led" salmonellas. In America outbreaks of sal-ella food-poisoning are not caused by dried egg, h few people eat; but it is obvious that their raw s eggs, like our duck eggs, are often infected. A recent ical Research Council report[5] should convince those doubt the potential danger from dried egg. breaks of infection caused by *S. oranienburg*, *ontevideo*, *S. tennessee*, and *S. sundsvall* are described, there have been many cases caused by other types he newer salmonellas. Clinically the disease caused hese alien salmonellas generally lasts from 2–3 days, sometimes it lasts 2–3 weeks with symptoms not ke typhoid fever. It has been stated that human iers of salmonella organisms are comparatively rare, one should remember that the patient can, and lly does, infect others during his illness and for ral weeks after apparent recovery.

hile human infection from dried egg can readily revented by following the Ministry of Food-recipes, important to know whether the new salmonella s have found any other animal home in this country. M.R.C. report tells what has happened to British . Mesenteric lymph-nodes from over 5000 pigs were mined and 2·5% were found to be infected. There e 17 different species of salmonella and of these 12 not been found in a similar investigation carried out re the war. As all but 3 of the 12 new types were recovered from dried egg, and as it was customary to discarded dried egg to pigs, there can be little doubt he source of infection. It will be of interest to find out ther the new salmonella are merely squatters among pigs or whether they have set up permanent residence. er domestic animals may also have been invaded but re is no information on this point. In America nestic hens and turkeys suffer severe attacks of nonella infection, and it is possible that our own s may have acquired some of these new infections. th the British poultry-farmer, who already knows the ravages caused by *S. thompson*, and the doctor agree that the native salmonellas need no nforcements.

THE CASE OF MR. BOWMAN

ROM statements appearing in the lay press it seems t Mr. D. W. Evans, coroner at Newport, Monmouth-re, when holding an inquest last month on Mr. J. M. wman, criticised the treatment he received from the st Middlesex County Hospital. The Middlesex County ncil, who had no opportunity of being represented the inquest, have sent us an account of the facts m their records.

Ir. Bowman, who was about 74 years of age, fell and ke his wrist on July 8. He was taken to King Edward's spital, Ealing (which does not come under the Middlesex nty Council), where his fracture was reduced and put up plaster. He was then discharged for outpatient treatment, is customary with cases of fractured wrist. On attending t day as an outpatient he appeared somewhat sleepy d had some bladder trouble. King Edward's Hospital d no vacant bed, but arrangements were made by telephone him to be admitted to the West Middlesex, where the ualty officer found him a bed in the acute surgical ward hout delay. He was taken there at once by ambulance.

The Middlesex County Council state that he was mitted to their hospital for the treatment of his dder trouble. While he was there a slightly peculiar ntal condition was noticed, which gave the impression senile decay but might have been attributable to the adder trouble. The latter quickly responded to treat-ent and on July 13 he was considered fit for discharge. He was advised when he left the West Middlesex to resume attendance at King Edward's Hospital for further treatment of his fractured wrist. His relatives, however, wished to take him back to Monmouthshire, and since in the opinion of the medical staff he was fit for this journey he was accordingly discharged. He needed help in dressing because he was an old man with his arm in plaster; but he was able to walk to the door of the ward, whence he was taken by wheel-chair to the lift, and then to a waiting car.

The subsequent history of the patient has been published; he died in hospital, a few days after his return to Newport, from the effects of a fractured skull.

The Middlesex County Council wish it to be clearly understood that any assertion that young patients are admitted more readily than old ones cannot refer to the West Middlesex or any other hospitals under the control of the council. As soon as the casualty officer had been satisfied that this was a proper case for inpatient treatment, he arranged for Mr. Bowman to be admitted. Such inquiry is necessary because of the great shortage of hospital beds. The help given by the staff in getting Mr. Bowman up was only required because he needed dressing. Any suggestion that he was unnecessarily discharged, or compelled to leave the hospital, the council affirm, is entirely unfounded.

THE PARENT AND THE DEAF CHILD

WHEN a child is discovered to be deaf parents are likely, at first, to be despondent, and very soon to fall into the habit of guiding the child by gestures. Mr. A. W. G. Ewing, PH.D., and Mrs. Irene R. Ewing point out, in a new pamphlet[1] addressed to parents, that few things could be worse for the child. The first task of the parents, they say, is to look at the child hopefully and assess his abilities: if his physical attributes are otherwise good and his intelligence normal, no matter how deaf he is he can learn to understand speech and to talk. A hearing child normally learns his first word or two because those words have caught his interest and he has associated them with meaning—he learns most readily what he hears most often. In the case of the deaf child the parents must take "every possible natural opportunity of putting words into his eyes instead of his ears."

Whatever the child's age when the deafness is discovered, the parents should begin to speak to him in the same way and in the same words as they would use if he could hear; but they must make sure that the child is looking at them when they speak. Like the hearing child, he will first understand meaning mainly from the mother's expression, but, unlike him, cannot get a further clue from her tone. The words used must be spoken plainly but not mouthed, and the child must get hundreds of opportunities of seeing words spoken, just as the hearing child gets hundreds of chances of listening to them. Because words cannot be seen as plainly as they can be heard, and because the deaf child only learns while he is looking at the speaker, progress in lip-reading is much slower than progress in the understanding of speech by the hearing child. Parents are advised to place the child with his back to the light, so that light falls on the faces of those speaking to him. "Baby" talk should be used no longer than it is with an ordinary child, but simple words should be preferred at first, and the expression on the face of the speaker should help to make the meaning clear. Once the child has begun to watch and lip-read, the length of the words does not matter: the Ewings have known a child of two lip-read "blackboard" and "motor-car." Given plenty of chances

OPPORTUNITY IN INDIA

LAST week 163 years of British rule in India came to an end with the formation of Pakistan and India as self-governing Dominions. On Aug. 14 some of the medical aspects of this change were discussed at a gathering in London called by Lord Moran, P.R.C.P., to hear Dr. R. G. Cochrane, F.R.C.P., principal of the Mission Medical College at Vellore in the Madras Presidency.

When it was known that India was really to have independence, Dr. Cochrane said, the tension snapped and the attitude towards Britain changed overnight. But fewer and fewer British doctors will be going to India, and the governments are likely to want official services to be manned by Indians. In this situation scientific standards are threatened by the backward pull of Eastern medicine, while professional integrity must be weakened by any weakening of the Christian ethic. If the mission hospitals disappear the Christian ethic will disappear too, and if that happens Western medicine will inevitably go into eclipse. It is essential, moreover, for India to have independent voluntary hospitals able to set a standard for the government institutions. In Madras a health minister whose wife was an Ayurvedic practitioner recently tried to establish five colleges of Ayurvedic medicine and induce the University of Madras to recognise this subject; and though the proposal was defeated it could be revived by a turn of the political wheel. It was felt that the only way to counter such retrograde influences was to create a medical college with an international reputation and train men and women who would follow its standards. To meet the challenge Vellore was converted from a lower-grade school, preparing students for the L.M.S. diploma, into a university college providing the educational background for positions of responsibility. The difficulties of finding a good enough staff are being overcome, and if money is forthcoming for the next few critical years Vellore may be able to do more to influence research and education than any other institution in the East. Though he himself is especially interested in leprosy, Dr. Cochrane felt that nowhere is this lead needed more than in psychiatry, where India is at the stage of England 200 years ago. Today there is a great opportunity, and Vellore College, a joint effort of the Churches of half a dozen countries, could do much to cement the friendly relationship with Indians which we all so much desire.

In response to questions Dr. Cochrane said that a proportion of Indians have an undoubted aptitude for scientific work, but in the official institutions research is apt to be crippled by lack of staff and consequent lack of time. Moreover many Indians are strangely attracted to Ayurvedic medicine, just as laymen in England are attracted to bone-setters. Dr. Cochrane agreed with Mr. Ian Orr and Sir Philip Manson-Bahr that the study of Ayurvedic remedies should go on, but he described Ayurvedic medicine in general as that of the Middle Ages and worse. Sir Francis Fraser spoke of the training of future Indian teachers in Britain, where a first batch of 50 have already been placed, and pleaded for continuation of efficient selection of these students at the Indian end. Sir Weldon Dalrymple-Champneys echoed Dr. Cochrane's regret that the Bhore Committee's recommendations are likely to fall into the background. The Christian ethic, he said, is the only moral backing for medical practice in India, which without it must revert to the past. It is something not imposed on Indians against their will, but a source of strength and inspiration on which many Indians depend in their struggle against political and other forces opposed to science.

As Lord Mountbatten said to the departing last Sunday, British rule in India has ended b place is being taken by something far more valu friendship between the British and Indians. To friendship, which is needed on both sides, m could contribute much.

MORPHINE SUBSTITUTES

FEW doctors would care to be deprived of a therap tool of the power of morphine; indeed it is hard imagine what medical practice would be like without All the more pity, therefore, that this drug so captures those it relieves, in the trap of addiction. latest League of Nations bulletin[1] on the treatment drug addicts is well worth reading. Here is told the story of how one method after another has been adv as a certain cure, only for patient to relapse and d to recant. Mention is made, too, of oddities such the birth of morphine-addicted babies from mo addicted mothers.

Against this somewhat macabre background the search continues for a substance which will have al pain-relieving and sedative powers of morphine but of its danger of addiction, and recent months produced several papers describing new synthetic gesics thought to have these properties, 'Miadone', 'Amidone'), one of the latest of such substances said to be a promising morphine substitute. Thorp[2] studied its analgesic properties by electric pain-thresh determination in rats, while in this issue we publish preliminary report by Dr. Hewer and Dr. Keele on effects in man. Miadone in their opinion has a pot equivalent to morphine without some of the undes side-effects of the latter; but they by no means exc the possibility of addiction. A similar compound AM is reported on by Gentling and Lundy[3] who saw no of addiction in patients who had taken the drug weeks.

In studying what is written about synthetic substitu for morphine, one is struck by the attention paid to constipating effect, which most workers seek to elimina No doubt they are right so far as the majority of pati are concerned; but it should not be forgotten that is a body of people with afflictions of the colon w would be delighted were they given a harmless dr which would reduce the liquidity of their stools. If the search for a morphine substitute a substance found which is a good "constipator" but a poor an gesic, it should not be immediately discarded; a tho should be given to those with colitis or a colost who might have a use for it. At the moment, cod is in high regard for this purpose, but more than patient has found that the dose of codeine that h sufficiently will also diminish his interest in life. Wh more, the drug is scarce, and very expensive.

SALMONELLA IN THE BACK-YARD

PLUM-SICKNESS is a countryman's description of Sonne dysentery; but this year dysentery bacilli a having a poor time. Instead, organisms of the salmonel group and particularly *S. typhi-murium* are ca much of the prevalent diarrhœa and sickness. Inad quately cooked duck egg continues to cause ma sporadic cases, and the public still does not realise th duck eggs should be boiled for at least eight minut A large outbreak in Essex[4] was lately traced to a d slaughter-house where the meat ration was contamin from an infected pig, but few recent outbreaks h been traced to rodents. It is the European type salmonella which are causing most of the serious ca though one might have expected trouble from some of t

NITROGEN TRICHLORIDE AND CANINE HYSTERIA

T. MORAN
C.B.E., D.Sc. Lpool, Ph.D. Camb.
rom the Research Association of British Flour-Millers, Cereals Research Station, St. Albans

ITROGEN trichloride (NCl_3) is used in many countries ughout the world, including Britain and the U.S.A., n improving agent for flour; commercially it is vn as "agene." For white flour of 70% extraction verage treatment is 3 g. per sack of 280 lb. of flour mg./100 g.), and for 85% extraction flour about 8 g. sack (6·4 mg./100 g.).

ellanby (1946) has shown that, with flour of 80–90% action, nitrogen trichloride in the amounts normally produces changes in flour which can give rise to eria in dogs. His paper was a preliminary report calls for much further work, including the answers ve questions:—

) Is the hysterical condition due to the absence of a itional factor (destroyed by NCl_3)?

) If it is not a nutritional deficiency, what is the identity e toxic agent or agents?

) Is wheaten flour essential in the diet—i.e., does NCl_3 with a constituent peculiar to wheaten flour?

) Has the toxic agent any effect on other animals, ding man?

) How far is the toxic agent influenced by the general osition of the diet?

he present paper describes the results of experiments gned to give information, particularly on the first e questions. In these experiments 85% extraction r was used throughout.

BORATORY PREPARATION OF NITROGEN TRICHLORIDE

 the laboratory a convenient method of preparing is to aerate an aqueous solution of chlorine in nonium-chloride or ammonium-sulphate solution. chlorine is added as freshly made chlorine water he solution of the ammonium salt, and the mixture llowed to stand in the dark for about 30 min. The tion is said to proceed according to the following ations:

$$Cl_2 + H_2O \rightleftarrows HOCl + HCl \quad \ldots \quad (1)$$

$$NH_4Cl + 3HOCl \rightleftarrows HCl + NCl_3 + 3H_2O \quad \ldots \quad (2)$$

h solutions of pH 4·4 or less, the ammonium derivative lmost entirely nitrogen trichloride with very little o- or di-chloramine. In our experiments we have ed the appropriate amount of chlorine water (0·1–N) to excess of a solution of 2% ammonium-chloride about 10°C in an amber bottle Under these itions the so-called nitrogen trichloride released the solution contains about 20% of free chlorine.

NGES IN FLOUR PRODUCED BY NITROGEN TRICHLORIDE

itrogen trichloride can act as an oxidiser—e g.:

$$NCl_3 + 3H_2O \rightarrow NH_3 + 3HOCl \quad \ldots \quad (3)$$

$$\rightarrow NH_4Cl + 2HCl + 3O \quad \ldots \quad (4)$$

$$\text{or } 2NCl_3 \rightarrow N_2 + 6Cl \quad \ldots \quad (5)$$

ould also form additive compounds at double hands g:

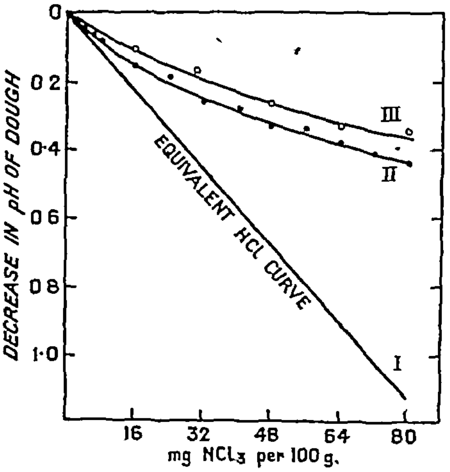
$$>C=C< + NCl_3 \rightarrow >C(NCl_2)-C(Cl)< \quad \ldots \quad (6)$$

$$\xrightarrow{H_2O} >C(NO)-C(Cl)< \quad \ldots \quad (7)$$

$$\text{or } \xrightarrow{H_2O} >C(NO)-C(OH)< \quad \ldots \quad (8)$$

t is also possible that NCl_3 might act as a chlorinating nt as in chlorine substitution reactions. The oxidation effect is obvious when flour is heavily treated, because it acquires a typical linseed-oil odour due to the oxidation of its fat. There is some evidence, however, that addition or substitution takes place as well as oxidation. Thus, if hydrochloric acid is added to flour, the curve relating the fall in pH to the amount of acid added is practically linear. This does not apply to nitrogen trichloride, even though from equations (4) or (5) the amount of acid formed is a fixed proportion of the amount of trichloride added. This is shown in curves I and II of the accompanying chart. In constructing these curves allowance was made for the fact that the nitrogen trichloride as prepared contains 20% of chlorine, which would, however, have no significant effect on the form of the pH curve. A departure from the curve obtained by the addition of HCl alone is also observed if the flour is defatted (by extraction with petrol ether) before it is treated with NCl_3, suggesting that addition or substitution compounds are also formed in the non-fat portion of the flour.

In the report of the Departmental Committee on the Treatment of Flour with Chemical Substances (Ministry of Health 1927) the suggestion is made that, in the treatment of flour with NCl_3, chlorine enters into parts of the protein molecule, particularly in the tyrosine and tryptophane groupings. In an attempt to check this we have carried out an extensive series of estimations of many of the individual amino-acids in flour (including tryptophane but not tyrosine) before and after treatment with NCl_3. In no case was any change observed in the apparent content of any of the amino-acids. The microbiological technique was used, and as this requires a preliminary hydrolysis for six hours with 2 5 *N* HCl (or, in the case of tryptophane, 0·4% baryta) it is obviously not too satisfactory, since unstable substances would be destroyed. It is therefore of some interest that a water extract of flour which contains tryptophane available to *L. arabinosus* without preliminary hydrolysis showed a progressive reduction in tryptophane content with increasing treatment with NCl_3; in the case of a flour given NCl_3 at the rate of 80 mg. per 100 g. (100 g. per sack) the reduction was 25%.



Curve I. Addition of HCl to flour.
,, II. Flour treated with NCl_3.
,, III. Defatted flour treated with NCl_3.

Mellanby in his experiments showed that the production of canine hysteria was not due to a deficiency of vitamin A. Vitamin E is said to be partially destroyed by NCl_3 (Engel 1942), but the addition of peanut oil was probably more than adequate to compensate for this. We have also found that even heavy treatment with NCl_3 has no effect on the B_1, riboflavine, and nicotinic-acid contents of flour. Measurements have also been made of the total pyridoxine-hydrochloride content of flour before and after treatment. This appeared to be of immediate interest in view of the finding by Chick et al. (1940) that epileptiform fits in rats fed for long periods on a purified synthetic diet could be prevented by the addition of pure vitamin B_6. The microbiological some children have started lip-reading at the age of a year and eight months. In children not recognised as deaf until they are two or three years old, lip-reading may begin within a month of the start of training. Gestures should be avoided at all costs: "every time one is employed instead of a word, an opportunity of helping the child to achieve lip-reading has been lost for ever." Indeed, the Ewings hold that where gestures are used instead of words they encourage dumbness. The child whose deafness has escaped diagnosis for as long as four years has become interested in doing things, and feels he has no time to spare for watching faces. He should be helped by the use of phrases dealing with action: "throw the ball," "wheel the cart," "eat your chocolate." His glance must be caught as often as possible and he must be talked to about things he is doing or wants to do.

Children who go deaf after learning to talk must be encouraged to keep up their speech, as well as to lip-read. Those who are born deaf babble like other babies. The parents must respond to this use of the voice, and later, when the child tries to use the words he has learned to lip-read, he must *always be encouraged and* praised for any kind of attempt. No attempt should be made, however, to teach him to say words, or to say them better: these are tasks for the trained and experienced deaf teacher.

DISTRIBUTION OF DOCTORS IN WAR-TIME

We in Britain have had our questionaries, but never on the scale of those addressed to some 50,000 American doctors by the Committee on National Emergency Medical Service, now analysed by Dickinson,[1] director of the Bureau of Medical Economic Research. The purpose was to find out what the American doctor thinks of medical organisation during the late war, and what improvements he would suggest. Replies were received from 2322 members of the profession who remained in civilian practice, and from 25,728 who served in the Forces.

During the war about 40% of practising doctors were taken into the Services, leaving the other 60% to look after 91% of the U.S. population. On the average the work which the civilian practitioner undertook was about 75% more in 1944 than in 1941—an increase of load which few other groups in the community had to bear. The health of the people improved during the war years; but in view of the difficulties under which the profession laboured it is not surprising that the question "could more doctors have been released for the Forces without endangering the welfare of the civilian population?" drew nearly three times as many answers No as Yes. In the Services, on the other hand, a very different problem arose—that of waste—and Dickinson thinks that the views of the ex-Service doctors merit serious attention, even though they did not see the situation from a high level. The majority recorded that (by civilian standards) too much time was given them to carry out their job; they estimated that only 72% of doctors employed were actually needed, and they held that too much time was spent in non-medical duties, such as administration and food inspection, which could have been carried out by laymen. Civilian hospitals, it was felt, were unnecessarily depleted of staff; yet there were idle beds in military hospitals which might have been used to relieve the pressure on them. It was admitted that military exigencies might well have increased the needs of the Services; but in the same way a serious epidemic might have increased the needs of the civilian population.

The civilians were asked, in four questions, to say what they thought should be done in the event of another war. The highest votes cast were in favour of the formation of mobile civilian medical teams to help areas strick by epidemics or by the newest forms of warfare. those answering thought they should take their t on Service boards (despite the administrative difficul so as to share out the burden among practition and three-quarters favoured establishment of a med board to decide on policy.

THE POLIOMYELITIS FILM

Mention of action proposed by a Ministry, particul where this involves Treasury authority, brings to a picture of long delays, punctuated by interdepartm memoranda. The Ministry of Health is to be con lated on having abjured such routine in making its for doctors on poliomyelitis. This film was con only on the 6th of this month; the idea was o to the Ministry on the 7th; and on the 11th the Tre agreed to meet its cost. The Ministry of Health rel to the Central Office of Information, which handles making for Government departments, and a unit commissioned to undertake the work. On the 1 final conference was held at the Ministry and the *ing script was decided; and that* same day started. Three days later this was completed; from the end of the month the film will be obt in all parts of the country, with projector and pro jectionist, from the regional offices of the Central O of Information, for showing to medical audiences.

The film, entitled *Early Diagnosis of Acute An Poliomyelitis*, was made with the help of Dr. W. Kelleher, invoked as a consultant by the Ministry, of Dr. R. C. Mac Keith, who acted as adviser to the which is directed by Dr. Brian Stanford. With a runn time of about 15 minutes, it describes the age-distribut of the disease in the present epidemic, and the ge symptoms; it gives an account of the signs that be elicited on examination of the central nervous sys and of some clinical techniques; and finally it refers simple measures for the prevention of spread.

THE TWO INTERNATIONAL CONGRESSES

The International Conference of Physicia convened by the Royal College of Physicians of Lond will meet on Monday, Sept. 8, under the presidency Lord Moran. After the opening session, to be held at college, it will divide into eight sections whose presid are: cardiology, Sir Maurice Cassidy; disorders of t chest, Sir Robert Young; dermatology, Sir Archib Gray; neurology, Dr. Gordon Holmes, F.R.S.; pædiatr Sir Leonard Parsons; psychiatry, Dr. Bernard Har social medicine, Sir Wilson Jameson; and gen medicine, Lord Moran. Daily until Friday, the sectio will meet at various halls and medical institut Social events will include a Government luncheon Monday, a reception at the college on Tuesday, and a banquet at Guildhall on Wednesday. Dr. G. B Mitchell-Heggs is acting as organising secretary.

The International Society of Surgery will ho its 12th congress in London from Sept. 14 to 21, follow by a visit of 100 members to Edinburgh from Sept. to 27. Dr. Leopold Mayer (Brussels) will preside; Pr G. Grey Turner is chairman of the British executiv committee, Sir Alfred Webb-Johnson, P.R.C.S., chairm of the consultative committee, and Mr. H. W. S. Wri hon. secretary of the congress. Some of the scientif sessions will be held in the great hall of B.M.A. Hou and others at University College; the inaugural ceremo will be at Lincoln's Inn; and the functions will incl the president's reception at the Savoy Hotel, a Gover ment reception at Lancaster House, and other gatheri at the Royal College of Surgeons, the Apothecari Hall, the Royal Society of Medicine, and the Brit Medical Association. The official dinner will be h at the Dorchester Hotel on Sept. 20.

[1] Dickinson, F. G. *J. Amer. med. Ass.* May 24, p. 360.

;e experiments show :

'hat the toxic factor is not associated with the starch ı of flour.

t is not associated with the fat; otherwise it would racted with petrol ether, absolute alcohol, acetone, loroform.

t is not a sterol; otherwise it would be soluble in orm and acetone.

conclusion therefore is that it is associated with the ı.* The fact that the 70% alcohol extract also ns the toxic factor supports this conclusion, since gliadin is soluble in this solvent. Owing to the ;al difficulties of evaporating large quantities of in the laboratory, no experiments have yet been l out with water or dilute salt extracts, though since two solutions contain protein they would also be ;ed to contain some of the toxic factor.

proteins of wheat are not well defined. Accordingly decided to carry out experiments on other proteins whether, when treated with NCl_3 and fed to dogs, would produce hysteria. Three proteins were ned—casein, zein, and gelatin. The last two were with the appropriate quantity of maize starch e a flour containing 12% of protein conditioned to 15% moisture content, and the mixture was then :d at the rate of 80 mg./100 g. The casein was :d alone at the rate of 136 mg./100 g. and then l with untreated potato starch equivalent to an ll treatment of the casein-starch mixture of ;./100 g.

Series IV

o.	*Protein-starch mixture*	*Symptoms*
10	Casein (Glaxo Light-White)	Running and convulsive fits in 24 hours
14	Zein (Glaxo pure)	Running and convulsive fits in 24 and 48 hours
d 15	Gelatin (Spa Brand)	Very slight running fits with both dogs after 10 days. Experiments then discontinued

)gs 8, 10, and 14 died, but dog 1 continued for some on the same diet but containing untreated zein; quickly recovered.

nally, as a further justification for identifying the ts of low and high levels of NCl_3 treatment, two were fed with five times the normal amount of ıed-out gluten from flour treated at the normal mercial rate of 8 mg./100 g.

Series V

Dog. no.	*Symptoms*
7	Convulsive fits after 3 days
11	Convulsive fits after 4 days

parate experiments showed that the high level of ein did not in itself produce hysteria or any other ırmal symptoms in dogs fed at the same level of en from untreated flour for 21 days.

DISCUSSION

ellanby (1946) has reviewed the more important ature on the subject.

he experiments here described show that the canine :eria produced by a diet containing flour treated with ogen trichloride is caused by a toxic agent and not a deficiency in the diet. Further, this toxic factor is ciated almost entirely with the protein fraction is relatively insoluble in the normal organic 'ents—absolute alcohol, chloroform, acetone, and rol ether.

Another important point is that the condition can be just as readily produced by the products of the interaction of casein and zein with nitrogen trichloride. Gelatin can also produce the toxic factor though apparently in much smaller amounts; this may, however, be connected with the more horny nature even of powdered gelatin compared with casein and zein.

In looking for this toxic factor, which may be present in exceedingly small amounts, we must not overlook the fact that inevitably these three proteins contain traces of impurities which may possibly react with the nitrogen trichloride. Even so, the fact that zein produces the toxin suggests that glycine, tryptophane, and lysine are not involved, since they are said not to be present in this protein in significant amounts.

It is tempting to carry this analysis further by comparing the amino-acid composition of the three proteins; but more experimental work is required before one is justified in giving better definition to the toxic substance. At the moment it looks as if it is of the nature of a protein poison or proteose mentioned by Clark (1940), the nitrogen trichloride reacting with a particular unit in the protein molecule.

The Ministry of Health report (1927) named tryptophane and tyrosine as the amino-acids likely to be involved, but the results with zein seem to rule out tryptophane.

Just recently attention has been drawn to experiments in America on the beneficial effects of feeding glutamic acid to epileptic children, and the fact that it is the only amino-acid known to be metabolised by the brain (*British Medical Journal* 1947, *Lancet* 1947). This acid predominates in cereal proteins and in casein, while it is present only in small amounts in gelatin. In following up this possibility we have so far been unable to produce hysteria by feeding casein hydrolysate which had been treated heavily with nitrogen trichloride.

No response has so far been obtained from the guinea-pig, the only other animal tried, when fed on flour treated with NCl_3. The flour beetle (*Tribolium confusum*) gives a response in that its life-cycle is retarded, but closer examination indicates that the mechanism is probably different from that involved in canine hysteria; this work will shortly be published. Work on the general problem is being continued.

CONCLUSIONS

(1) Canine hysteria has been produced within 24 hours by the use of NCl_3 in amounts which are, however, considerably in excess of those used in milling practice.

(2) Nitrogen trichloride reacts with wheat protein, casein, zein, and gelatin, producing substances which give rise to canine hysteria. The symptoms rapidly disappear when the dogs are given the same diet which has not been treated with NCl_3.

(3) The production of these substances appears to involve a particular structure in the protein molecule which does *not* include lysine, tryptophane, or glycine.

Several of my colleagues, including E. N. Greer, J. B. Hutchinson, J. G. Heathcote, R. G. Booth, and G. G. Grindley, have contributed to the work described in this paper. I have also had the benefit of discussions on the problem with Lord Horder, Sir Edward Mellanby, Prof. E. C. Dodds, and Sir Robert Robinson.

---

* is not generally realised that gluten simply washed out from a dough of flour and water contains 70% of the original fat in the flour. This simple method of approach cannot, therefore, be used to decide whether the toxic factor is associated with the protein in the flour.

method was used (Barton-Wright 1945), and the following results were obtained on an 85% extraction flour:

	Pyridoxine-hydrochloride content
Control flour	4·9 µg./g.
Flour treated with 9 6 mg. of NCl_3/100 g. ..	4·9 „
„ „ „ 80 „ „ „ ..	4·8 „

On the whole, therefore, there is no evidence that a *vitamin deficiency is the causal factor in canine hysteria.* Experiments on dogs support this view.

EXPERIMENTS ON DOGS

Mellanby has described in detail the symptoms of canine hysteria, and our experience is in accord with his observations. There are in general four stages:

(1) The dog is obviously off colour, takes little interest in his surroundings, and walks slowly, but in general coils himself up as if to sleep.

(2) There is much weakness in the hind legs, and he may lift his forelegs high when walking. He will often "hide" his head low down in a corner of the cage.

(3) Running fits; the dog, apparently apprehensive, will, after some preliminary haphazard quick movements, run round and round the cage, sometimes running into the walls, upsetting its water and food, and obviously in a state resembling panic. It may howl and bark.

(4) Epileptiform or convulsive fits usually but not always follow running fits. The animal lies on its side, its jaws champing, foaming at the mouth, and legs beating the air. If these fits are severe and many, the dog will die.

In all our experiments we have followed the diet used by Mellanby—i.e., skim-milk powder 20 g.; lean meat 15 g.; peanut oil 10 ml.; bakers' yeast 5% of the cereal; flour 100–300 g. The flour was first made into a cream with water and then cooked in a steamer for 90 min. at 1/2 lb. pressure.

In the first experiment three dogs (nos. 1, 6, and 9) were given this diet, the flour having been treated with NCl_3 *at the rate of 80 mg. per 100 g. (100 g./sack).* Within 24 hours all three dogs had shown the symptoms already described, including running and convulsive fits. After this one meal they were put on the same diet but containing untreated flour, and they all recovered within a few days and thereafter behaved as apparently normal healthy dogs.

The fact that the symptoms were precisely those described by Mellanby is reasonable evidence that the same mechanism was at work, but that the much higher dose of NCl_3 was sufficient to produce the disease rapidly compared with the 2–4 weeks found by Mellanby for the ordinary commercial treatment of some 6·4 mg./100 g. Further, Sir Edward Mellanby informed me that he had not produced the disease with flour treated only with chlorine. This was confirmed by us later in this work, because a diet containing flour treated with chlorine, at the rate of 112 mg. per 100 g., had no effect on dogs 9 and 13, even after 21 days. Since the heaviest treatment of NCl_3 used in this investigation contained only 16 mg. of free chlorine per 100 g. of flour, the chlorine per se can be ruled out as the cause of the hysteria.

In a further experiment two groups, each of two dogs, were given diets containing flour treated at 20 and 40 mg NCl_3/100 g. Two similar groups were given flour treated at 80 mg./100 g. but diluted with untreated flour to give an average overall treatment of 20 and 40 mg./100 g.

This series of experiments (II) was instructive since it showed that there is no additional toxic factor produced at the high level of NCl_3 treatment compared with the lower level of 20 mg./100 g. The fact that, at the low level of 20 mg./100 g., precisely the same symptoms were produced as with the heavily treated flour diluted to this low level is further evidence that canine hysteria is not caused by a deficiency in the diet. Perhaps even more convincing is the fact that the disease can be after one meal.

Series II

Dog no.	*Flour*	*Symptoms*
2	Treated 40 mg./100 g...	Running fits .. ..
3	Diluted to 40 mg./100 g.	Running and convulsive fits .. ..
16	Diluted to 40 mg./100 g.	Unwell but no fits .. *
17	Treated 40 mg./100 g...	Unwell but no fits .. *
7	Diluted to 20 mg./100 g.	Running and convulsive fits .. ..
14	Diluted to 20 mg./100 g.	Running fits .. ..
9	Treated 20 mg./100 g...	Running and convulsive fits .. ..
15	Treated 20 mg./100 g...	Running and convulsive fits .. ..

* Experiment discontinued after 7 days.

Dogs 16 and 17 were anomalous, but they than three months old, and later work co older dogs, 4–6 months old, were much more Mellanby observed the same point. We have as factual evidence that breed plays an important part

Since in this work we were concerned primarily origin and identification of any toxic factor and with the physiological aspects of canine hysteria, it reasonable to continue using flour treated with at the high level of 80 mg./100 g. Further, there be no objection to using the same dogs once they been given a period to recover from an attack; as it was clearly an advantage to use a dog which known to be sensitive to the toxic factor.

The next series of experiments was planned to whether the *toxic factor is associated* with the carbohydrate, or the protein, of flour. The foll table gives the broad results:

Series III

Dog no.	*Fraction of flour under test*	*Symptoms*
4, 7, and 11	Residue after removal of water-solubles	Running and fits in 23–72
2 and 5 ..	Residue after treatment with petrol ether	Running and fits in 18 and
13 ..	Evaporated petrol-ether extract	None
6, 7, and 11	Residue after treatment with absolute alcohol	Convulsive fits hours
2 ..	Evaporated absolute-alcohol extract	None
3 and 12..	Residue after treatment with 70% alcohol	Running fits in 96 hours
4 and 11..	Evaporated 70% alcohol extract	Running and fits in 24 and
1 and 13..	Residue after treatment with chloroform	Running and fits in 23 and
12 ..	Evaporated chloroform extract	None
1 ..	Evaporated acetone extract of flour	None
13 ..	Wheat starch treated at 80 mg./100 g.	None after 6 days
12 ..	Maize starch treated at 80 mg./100 g.	None after 6 days

In the experiments with the extracts of petrol absolute alcohol, chloroform, and acetone, each of dogs was given for several days the equivalent of quantities of flour—e.g., in the case of absolute al the dog was given each day for three days the extracted from 1600 g. of flour. It is therefore safe to that the toxic factor is relatively, if not compl insoluble in these four solvents. The residues on other hand still retained it.

nce we can't build any hospitals yet, we may as be thinking about it; so I took the opportunity re leaving Switzerland of visiting one of its most ern institutions. It was more impressive materially, its 950 beds, than it was psychologically, although was a beautifully light and spacious entrance-hall ong contrast to the air of "abandon hope all ye who here" which surrounds the outpatient hall of my ıospital. But it is, of course, too big, and 500 beds ce the Goodenough Committee, much more likely ove the right number than 1000. It really boils to planning the hospital round the human beings giving the patient a heavily weighted score rather discussing whether this or that number of beds is mical to run or easy to administer.

itish medicine appears highly socialised compared Swiss counterpart, and it was with interest that med that the patients in the hospital were divided three classes, the first, in private single rooms, ibuting 20 francs a day, but the third in small wards , contributing about 4 francs a day; and I heard rather a shock that, although the clinic chief visits first-class patient daily, he only sees the third-class nts once a week.

e medical records in this hospital are typed, many em by one of the assistants of the chef-de-clinique ıse of the inability of the typist to deal accurately the nomenclature. I decided to try this on when in my own department, but second thoughts sted that I wouldn't have much luck. Democracy ts cost. The internal arrangement of the notes was orderly; but on the other hand they are still d within easy reach of the patients, and eventually in unwieldy great tomes.

ıe was left with the impression of a large hospital ajestic material design, but in which the tendency o think of the patient rather as a unit than a person, one felt not unhappy about our trend of thought even though we lack the wherewithal to convert it reality.

*

ıd now down with a bump to an earth of coalmining shipbuilding. It often seems to me that one of the s to tackle the environmental problems of the pit ld be to develop a system of personnel medical officers ogous to that used so successfully by the R.A.F. ng the war, where doctors of wing-commander ority studied working conditions at first hand and made immediate appropriate suggestions or took problem along to a team of research-workers. Lighting e subject I should start with, as we know quite enough ıt its rôle in the ætiology of accidents and nystagmus: is it that below ground the legal upper limit is some rable decimal of a foot-candle, when in a factory above ground it is nearly 10? Most of these problems are to be solved by applied engineering of one sort and another, and one's feeling is that a combined team with its members of equal rank, irrespective of profession, is the way to set about it. As for shipbuilding—but here an almost complete absence of basic data makes the situation, if anything, a stage more primitive than that found in mining.

* * *

Your young peripatetic colleague's experiments in temporary immobilisation of poultry by a chalk line interested me because I remember my father showing me much the same thing some 35 years ago. His technique of calcilinear fowl-hypnosis was however somewhat different: instead of leading the reluctant hen to the chalk line he led the chalk line away from the already stationary hen. He first held the hen's head to the ground with one hand, and with the other he then drew a quite short chalk line away from the point of the beak so that the distal end disappeared behind a nearby brick or stone. Then he let go, not always gently. The hen would stand stupidly and unblinkingly immobile —perhaps squinting a little; I don't remember—for what seemed several minutes, after which she would slowly and dazedly lift her head, shake it sorrowfully, then apparently awaken to a sudden realisation of the enormity of her folly, and scurry away, protesting volubly at her public degradation. If she was forcibly removed before her natural time, her beak would cling to the ground and you could almost fancy a faint "twang" or "ping" as the psychological tether snapped.

Obviously a worthy subject for further research. Has anyone tried two hens side by side? or at opposite ends of a line?

* * *

Early in October, 1945, a Naval force from H.M.S. *Anson* landed at Hong-Kong and began the difficult task of rebuilding His Majesty's law and order upon the ruins left by the little yellow men. From then until May 1 of last year this rehabilitation was left to the Armed Forces, and a good job they made of it. It has never been easy to impose Occidental morality and social machinery upon the Oriental, but they did it. The colony was policed, fed, cleaned, guarded, and doctored. When the Civil Administration returned to office, the Military handed over a going concern.

This morning I entered my clinic (two rooms in an old government building) to find a smartly dressed and obviously consequential young Englishman busily taking measurements of the walls and the floors, whilst a clerk recorded the findings in a fat exercise-book.

"What," I said, "are you up to now? Are you from the P.W.D.?" (For one wild moment I had the foolish idea that my six-month-old request for a little whitewash on the blotched and peeling walls had met with action. Silly of me.)

"No," said the young man. "I'm the Assessor."

"And what," I asked, "do you hope to assess here?"

"We're measuring up all the space used by the Service departments during the Military Administration. They're going to be charged rent. So much a foot."

* * *

Subbiah was very anxious to get the job we advertised. It offered him good pay and prospects, but unfortunately demanded a certain educational standard. He had sat his matriculation several times but had failed on each occasion. To the Indian the very sitting of an examination confers a definite status, and repeated sittings are by no means a disgrace. Subbiah thus thought it wise to include all these details in his letter of application, which was an extraordinary document. He gave a long account of his life-history, education, and previous employment, and he backed up the letter with a sheaf of probably worthless testimonials, all of which described his abilities in glowing terms. He must have given a great deal of thought to the explanation of his repeated examination failures, and his final excuse was most ingenious. "The last examination I work for very hard and I am sure to pass but I fail because I have scabies"; and in case the significance of this was not clear: "my bottom itch so much I cannot sit still to write the paper."

Anxious patient to neurologist: "Are you—forgive me if I'm being rude—a psychiatrist?"

WORKING CONDITIONS IN IRON FOUNDRIES

ADVISORY COMMITTEE'S REPORT

IRON founding is one of the oldest trades, and the work is intrinsically heavy, hot, and dusty. In Great Britain there are about two thousand iron foundries which differ greatly in size and methods of production; and the castings made in them vary in weight from an ounce to 150 tons. In some, especially the modern mechanised ones, the conditions are good, but in others, such as small jobbing foundries, the buildings, production methods, and working environment have not changed materially during the last fifty years; and it is becoming increasingly difficult to get people to work in what are regarded as unpleasant trades.

In 1945 Sir Wilfred Garrett, chief inspector of factories, set up a joint advisory committee,[1] composed of representatives of the industry, trades unions, and the Factory Department, to advise him:

> "on the most effective methods of implementing certain requirements of the Factories Act, 1937, and on other cognate problems in ironfoundries, particularly those relating to cleanliness, lighting, ventilation, and maintenance of satisfactory atmospheric conditions, provision of washing facilities and accommodation for workers' clothing and other welfare and health services and amenities."

The committee's report,[2] which has now been published, contains a series of recommendations which, if adopted, should go far towards making iron founding a more attractive trade, and to furthering the efforts which have already been made in some iron foundries to improve conditions. Throughout its deliberations the committee kept three main objectives in mind: (i) the provision of better amenities and more comfortable and healthy working conditions; (ii) the improvement of the appearance of iron foundries through better cleanliness and orderliness and more light and colour; and (iii) improvement of the atmospheric conditions by prevention or removal of dust, smoke, and fumes.

Detailed recommendations are made to secure cleanliness, and one of these says that all floors should be maintained firm and level and should be constructed of concrete, brick, or other suitable materials unless it can be shown to be necessary to have a sand floor at any part of a foundry. The firm floor is easier to keep clean, though it may be broken up when heavy castings are dumped on it. The use of vacuum methods for removing dust and dirt is strongly recommended. Under the heading of "good housekeeping" suggestions are made for keeping the foundry tidy—a factor which not only improves its appearance but contributes to safe working, better morale, and production efficiency.

As regards temperature, it might be thought that the main problem is to keep a foundry cool; but this is only so in parts around the furnaces and metal-pouring operations. In other parts it can become very cold, and it is not uncommon for work to be delayed because the sand has frozen overnight. It is recommended that the temperature in a foundry should not be less than 50°F one hour after work has begun. If the outside temperature is under 30°F it is regarded as reasonable that the inside temperature should not be less than 20°F higher. Methods for heating the workrooms should not include open coal or coke fires or mould driers. An "open fire" is defined as one not provided with a flue to take the products of combustion to the outside air.

The lighting in foundries should comply with the standards laid down by a code of regulations made in 1941, and additional lighting should be provided where the nature of the work demands it. For instance, 20 foot-candles should illuminate the work of fine core making and moulding. The lighting will be improved if the walls, ceilings, and machinery are painted with light colours, and the industry is urged t away from its customary drab colour-schemes or l schemes.

The provision of washing facilities and accommoda clothing is now compulsory under the Factories Act, 1 but so far standards have not been laid down. B especially of the needle or shower type, are recommende those persons engaged on hot, dirty, and arduous jobs. W basins, one for every 10 persons employed, should be ins hot water should be laid on, and clean towels, soap, and brushes should be available. Changing-rooms and l for clothing should also be provided, and all these am should be under the care of a responsible person. Ca or mess rooms should be provided, and the taking of in work-rooms should be prohibited.

It is customary to use open fires in foundries for a numbe purposes, such as warming the work-rooms, drying ladle moulds, and in a process called "burning," a technical which is not explained in the text.[3] The committee is of the opinion that the use of such fires should be a and that the industry should try other methods. It is mended that a ladle-drying station should be arranged i new foundries and, wherever practicable, in existing Moulds should be dried in stoves, or where this is not p by mould driers, which are portable devices consisting coke fire blown upon by a fan or by compressed air; would be little risk of injurious or offensive fumes or being evolved from them. Cores, which consist of sand binding materials such as dextrin and linseed oil which heating give off irritating fumes, should be dried in prope ventilated stoves. When those cores are being broke after the metal is cast, any fume given off should be qu removed from the work-rooms.

One of the dustiest of foundry jobs is the "knock-out a term used to describe the various ways of removing cast from the sand moulds. A series of recommendations is for controlling the dust during the knock-out in types of foundries, such as mechanised, heavy and job and light and green sand foundries. The methods su include the application of exhaust ventilation and sep of the process from other foundry jobs. Another job is the "dressing" of castings, which is done in ways by wire brushes, hand hammers, rumbling barrels, gr ing wheels, or blasting apparatus. It is recommended the operation should be concentrated in an area of foundry set apart for the purpose, or in a separate r and that it should be done under exhaust ventilat a high standard of general ventilation should als maintained.

In the section on health reference is made to incidence in iron foundries of silicosis and pneumoconi dermatitis, rheumatism, and "dead hand" in work using pneumatic tools. The committee's terms reference did not include the assessment of h risks, but it was inevitable that in the considerat of amenities such matters should be discussed. committee is of the opinion that the iron-fo industry, in common with other industries, would b greatly by the provision of medical and nursing s to help in maintaining the health and reducing occupational risks of workers. It also recognises desirability of appropriate periodical examinations workers, and it recommends that medical and n services should be provided as soon as possible. question of noise in factories is mentioned, and foundries the committee thinks this merits fu investigation. Finally, a section is devoted to practical and technical matters which the comm thinks should receive attention from those who inten build new foundries.

The committee adds two comments: first, in comp with other old industries, many iron foundries s from being housed in poor premises built in days too little attention was given to working conditions, this will remain a fundamental defect until rebuil can be undertaken; and secondly, the committee w welcome an increased use of mechanical aids and labour-saving devices.

*

ıce we can't build any hospitals yet, we may as
be thinking about it; so I took the opportunity
e leaving Switzerland of visiting one of its most
ern institutions. It was more impressive materially,
its 950 beds, than it was psychologically, although
was a beautifully light and spacious entrance-hall
rong contrast to the air of "abandon hope all ye who
here" which surrounds the outpatient hall of my
hospital. But it is, of course, too big, and 500 beds
ace the Goodenough Committee, much more likely
rove the right number than 1000. It really boils
n to planning the hospital round the human beings
giving the patient a heavily weighted score rather
discussing whether this or that number of beds is
omical to run or easy to administer.

ritish medicine appears highly socialised compared
ts Swiss counterpart, and it was with interest that
rned that the patients in the hospital were divided
three classes, the first, in private single rooms,
ributing 20 francs a day, but the third in small wards
x, contributing about 4 francs a day; and I heard
rather a shock that, although the clinic chief visits
first-class patient daily, he only sees the third-class
ents once a week.

ıe medical records in this hospital are typed, many
ıem by one of the assistants of the chef-de-clinique
use of the inability of the typist to deal accurately
the nomenclature. I decided to try this on when
in my own department, but second thoughts
ested that I wouldn't have much luck. Democracy
its cost. The internal arrangement of the notes was
orderly; but on the other hand they are still
ed within easy reach of the patients, and eventually
in unwieldy great tomes.

ıe was left with the impression of a large hospital
ıajestic material design, but in which the tendency
to think of the patient rather as a unit than a person,
one felt not unhappy about our trend of thought
, even though we lack the wherewithal to convert it
reality.

*

ıd now down with a bump to an earth of coalmining
shipbuilding. It often seems to me that one of the
s to tackle the environmental problems of the pit
ld be to develop a system of personnel medical officers
ogous to that used so successfully by the R.A.F.
ng the war, where doctors of wing-commander
ority studied working conditions at first hand and
made immediate appropriate suggestions or took
problem along to a team of research-workers. Lighting
e subject I should start with, as we know quite enough
it its rôle in the ætiology of accidents and nystagmus:
is it that below ground the legal upper limit is some
rable decimal of a foot-candle, when in a factory above ground it is nearly 10? Most of these problems are to be solved by applied engineering of one sort and another, and one's feeling is that a combined team with its members of equal rank, irrespective of profession, is the way to set about it. As for shipbuilding—but here an almost complete absence of basic data makes the situation, if anything, a stage more primitive than that found in mining.

* * *

Your young peripatetic colleague's experiments in temporary immobilisation of poultry by a chalk line interested me because I remember my father showing me much the same thing some 35 years ago. His technique of calcilinear fowl-hypnosis was however somewhat different: instead of leading the reluctant hen to the chalk line he led the chalk line away from the already stationary hen. He first held the hen's head to the ground with one hand, and with the other he then drew a quite short chalk line away from the point of the beak so that the distal end disappeared behind a nearby brick or stone. Then he let go, not always gently. The hen would stand stupidly and unblinkingly immobile —perhaps squinting a little; I don't remember—for what seemed several minutes, after which she would slowly and dazedly lift her head, shake it sorrowfully, then apparently awaken to a sudden realisation of the enormity of her folly, and scurry away, protesting volubly at her public degradation. If she was forcibly removed before her natural time, her beak would cling to the ground and you could almost fancy a faint "twang" or "ping" as the psychological tether snapped.

Obviously a worthy subject for further research. Has anyone tried two hens side by side? or at opposite ends of a line?

* * *

Early in October, 1945, a Naval force from H.M.S. *Anson* landed at Hong-Kong and began the difficult task of rebuilding His Majesty's law and order upon the ruins left by the little yellow men. From then until May 1 of last year this rehabilitation was left to the Armed Forces, and a good job they made of it. It has never been easy to impose Occidental morality and social machinery upon the Oriental, but they did it. The colony was policed, fed, cleaned, guarded, and doctored. When the Civil Administration returned to office, the Military handed over a going concern.

This morning I entered my clinic (two rooms in an old government building) to find a smartly dressed and obviously consequential young Englishman busily taking measurements of the walls and the floors, whilst a clerk recorded the findings in a fat exercise-book.

"What," I said, "are you up to now? Are you from the P.W.D.?" (For one wild moment I had the foolish idea that my six-month-old request for a little whitewash on the blotched and peeling walls had met with action. Silly of me.)

"No," said the young man. "I'm the Assessor."

"And what," I asked, "do you hope to assess here?"

"We're measuring up all the space used by the Service departments during the Military Administration. They're going to be charged rent. So much a foot."

* * *

Subbiah was very anxious to get the job we advertised. It offered him good pay and prospects, but unfortunately demanded a certain educational standard. He had sat his matriculation several times but had failed on each occasion. To the Indian the very sitting of an examination confers a definite status, and repeated sittings are by no means a disgrace. Subbiah thus thought it wise to include all these details in his letter of application, which was an extraordinary document. He gave a long account of his life-history, education, and previous employment, and he backed up the letter with a sheaf of probably worthless testimonials, all of which described his abilities in glowing terms. He must have given a great deal of thought to the explanation of his repeated examination failures, and his final excuse was most ingenious. "The last examination I work for very hard and I am sure to pass but I fail because I have scabies"; and in case the significance of this was not clear: "my bottom itch so much I cannot sit still to write the paper."

Anxious patient to neurologist: "Are you—forgive me if I'm being rude—a psychiatrist?"

Letters to the Editor

FOOD

SIR,—Your leading article of Aug. 9 raises several important issues. You urge the Ministry of Food to publish the results of its surveys and researches into past and present eating habits in this country. If this was done there is no doubt that most of us would be astonished at the wealth of data actually known about recent and present food problems. This information is probably of a high order of accuracy owing to the considerable resources and the highly trained staff at the disposal of the Ministry for this work.

As you pertinently point out, the Ministry should enlist the support of doctors in explaining present-day feeding difficulties to the public. Patients often make derogatory (and, I think, mostly inaccurate) statements about the rations, and many professional colleagues do the same. Ignorance of data on the subject makes it difficult to combat the "prejudice and personal impressions" you speak of.

So much for the immediate issue. There is another aspect to this problem which seems to be extremely important. The growth of Government-financed research, medical and otherwise, proceeds apace. Where this is under the ægis of the Medical Research Council the results are published, but where it is carried out by Civil Service departments publication is not assured. Some of the facts may eventually see the light of day as political literature, which, rightly or wrongly, is often regarded as biased. This is a serious state of affairs when it is realised that increasingly large numbers of high-grade scientific workers are being employed in the Civil Service, which has financial resources and an organisation transcending in size those of other research-workers or groups of workers. This being so, data of considerable scientific importance—to do for example with the nutrition of this country—ought not to remain locked away in the files of a Government department, but should be published. Further they should not be published as official "hand-outs," nor necessarily as special publications, but in the medical journals. If anonymity was required only the office of the authors need be stated.

It is realised, of course, that this problem is far from simple, and that it raises the whole question of the necessity of secrecy in work done for the Government. However, facts about the nation's nutrition cannot be placed in the same class as those relating, for example, to atomic energy; and it is time the medical profession pressed for the most extensive publication of scientific information by the Ministry of Food.

West Middlesex County Hospital,
Isleworth.
N. F. COGHILL.

SIR,—It is indeed essential for the Ministry of Food to publish the results of surveys of the diets actually eaten by the different categories of the population. It is even more important to know, as you suggest, Sir, the exact figures of the amount of food moving into consumption, and the proportion allocated to various sections of consumers.

I may, however, perhaps comment on your statement that in this country "the level of food consumption is at least sufficient to prevent deficiency symptoms." I cannot agree with this, for two main reasons: (1) because we are not in possession of reliable statistics and results of surveys, and (2) because the incidence of minor or latent deficiency states has noticeably increased during the last year or two. Furthermore, I should like to point out that deficiency states are not caused only by inadequate dietary intake; in the clinical assessment of nutritional states conditioning factors—e.g., interference with ingestion, absorption and utilisation; increased requirements; and increased destruction and excretion—are also relevant. I feel that these factors are even more important now, since the present narrow margin which food-rationing allows us makes it very difficult, if not impossible, to counteract the factors by an increased or more balanced food intake. After seven years of rationing it may not be enough to consider the nation's nutritional state merely from the poi view of adequate intake.

London, W.1.
Z. A. LEI

SIR,—You might, I think, have gone furthe believe that the general failure of the Ministry of F to consult the medical profession may well extend to a failure to consult the Ministry of Health.
M.O.

ELECTRONARCOSIS

SIR,—Dr. Paterson and Dr. Milligan's article (Au raises again the question of the risks of electrical con therapy and its recent modification. L. C. Cook,[1] like authors, stresses the importance of a thorough m examination "with special reference to the circ and respiratory systems"; but apart from a note previous convulsive disorder they do not urge importance of eliminating diseases of the nervous s

Since 1942 I have personally known of three whose deaths were hastened by E.C.T. and which not reported in the literature.

1. A British soldier who presented mixed psychotic with no demonstrable organic basis was started on E.C He immediately developed meningitic symptoms and Post mortem a temporal-lobe abscess was found.

2. A West African soldier appeared to be a classical of endogenous depression with ideas of unworthiness guilt. While this form of mental illness was rare in West Africans, admitted to the base psychiatric unit condition looked typical and he was started on E.C The next day his temperature rose and he showed sig cerebral irritation. Lumbar puncture was done and t somes were found. He was given specific treatment but 24 hours later.

3. A female patient, aged 54, who was diagnosed as genous depression and who previously had had a cours E.C.T. with benefit, was given a second one. She devel incontinence of urine, ankle-clonus, and bilateral ext plantar responses. There was ataxia of all limbs and abdominal reflexes were absent. These gradually impro but several weeks later she was still slightly ataxic spastic. She left hospital and a couple of weeks later following a stroke.

There were two cases of G.P.I., one of whom nearly d following E.C.T. He was a soldier, aged 31, who was diagno as hysteria. It was later thought that there was sc phrenic deterioration and he was started on E.C.T. He not recover consciousness for two days, and after th flaccidity became spastic with grasp reflexes, &c. Lu puncture was diagnostic of G.P.I. The other case did react so grossly, but the condition was "unmasked" by E.C.T.

All these cases had been given careful ph examinations by independent physicians and one been examined by a neurologist. It seems that o disease of the nervous system also merits special refe prior to giving E.C.T. or electronarcosis. I think unlikely that these 5 cases are exceptional, and I a tempted to think that there may be others which ha not yet been reported.

Walsall.
M. St

DENTAL CARIES

SIR,—In reply to Dr. MacGregor's interesting comm of Aug. 2 I wish to make the following points:

1. Disuse atrophy in bones and muscles is obv and undisputed. Yet the how and why is l problematic and hypothetical. For the same r an attempt at an explanation of the physiol process in disuse odontoporosis would be prematur

2. The statement in my letter that changes in t due to disuse cannot readily be demonstrated by e radiographic or chemical analysis needs clarific The effects of disuse on the bones has been given c attention in radiological studies. In disuse atroph the bone, the changes appear early on röntgenol examination. They are readily detectable only in spongy trabecular structure, while demonstration in cortex is difficult or impossible until at an adva stage real narrowing of the cortex takes place. 0

---

[1] Recent Progress in Psychiatry, London, 1944, p. 44

he dense non-trabecular structure of the teeth, the
ographic method is of little use in attempting to
ct a reduction in density, as too many variable
ors enter in trying to estimate the density of a more
ss uniform shadow.

Examination by chemical analysis was considered
tisfactory as it has been demonstrated in disuse
phy of the bone that the chemical composition
ergoes no detectable qualitative alteration. The
iges represent merely a quantitative variation
ting the density of the tissue.

A comparison of the physical density of an
rently sound tooth of a western European and of a
itive native not affected by caries has not been
e to my knowledge. I observed that if Europeans
poor teeth start to chew sugar-cane, it is not a
occurrence that also apparently sound teeth break,
t I never saw or heard of in non-assimilated natives.
observation impresses me as an indication that
teeth in civilised man are structurally different
not merely superficially more exposed to the ravaging
ts of chemical agents in their diet. This structural
rence is not congenital as a few years of civilised
are sufficient to impair the condition of the teeth
ny native.

The assumption that enamel is a "lifeless" struc-
is not definitely established. Sognnaes was able
tect radioactive phosphorus, administered systemi-
, in the fully formed enamel of cats and dogs.

The fluorine content of drinking-water does not
a satisfactory clue to the varying incidence of
al caries. There are too many places with a very
fluorine content in the water and simultaneously
w caries incidence, and vice versa. The fluorine
ent of the drinking-water of Wellington, N.Z., and
es, Italy, is approximately the same. Yet caries
rs at a proportion of ten to one in Wellington.
iote a study made among the Indians in Mexico
Anderson et al. which concluded as follows: "the
rvation that nearly fifty per cent. of adult males
perfect teeth seems remarkable. . . . Chemical
nination of the water from several of the wells
rs 0·2 to 0·3 p.p.m. of fluorine. This is far below
ptimum usually stated to be desirable for preventing
s."

ere is no doubt that experiments will have to
fy some of the problematic points and to verify
lusions based on empirical knowledge.

Albans, N.Y. H. H. NEUMANN.

CRAMP AND SALT BALANCE

R,—In his article of Aug. 16 Sir Arthur Hall raises a
tion which has interested me for some years. I
e that salt depletion is a very rare cause of cramp,
ys excepting miner's cramp of which I have no
rience, and cholera, of which I have a little.

1940 I was consulted by an elderly civilian chaplain
ig the hot weather in Northern India. He had, of course,
sweating freely for several weeks, and complained of
iso cramps in the legs. I advised a teaspoonful of common
three times a day and the addition of as much salt as
ible to the ordinary meals. Next day the cramps went
did not come back that summer.

have never repeated this success: I have been
ulted many times in this country by elderly men
nocturnal cramp, but not one has improved with
um chloride. In fact, I cannot say that any treatment
been much good. It is hard to say what other factors
e much effect; long-standing ischæmia does not seem
ortant, for extreme cases of intermittent claudication
a poor reactive-hyperæmia test do not seem specially
uffer nocturnal pain. Incidentally, the pain produced
oing this test varies enormously.

nlike Sir Arthur, I saw no evidence of increase in
eptibility to cramp in those with disturbed salt
nce. Careful observation of large numbers of people
ng hot seasons did not bring to light complaints of
np, even where routine urine-testing showed gross
ciency in chloride excretion.

o while, once in a way, one may pick a winner in
ting cramp with salt, the odds are very long. Nor is relationship with poor blood-supply clear. It will be interesting to hear other opinions on this resistant and obscure symptom, both as to pathogenesis and treatment. For myself, I shall continue to try salt in cramp; it may relieve somebody again some day.

Hutton Mount, Essex. GAVIN THURSTON.

DISTRIBUTION OF STREPTOMYCIN

SIR,—In your issue of Aug. 16 a writer accuses you of complacency as regards the supply of streptomycin. You scarcely rebut the charge, and in attempting to do so you speak of "hesitation about diverting any large proportion of our limited resources." This lays you open to the charge from another angle.

Those who feel keenly about the ravages of tuberculosis and know that the fight depends fundamentally on money should never rest content with the attitude that the fight should be financed out of current revenues or contingent charity. Of course our money standards have recently been upset in several senses, but we suffer too because enlightened and sensitive people do not put the perspective with regard to our fight against preventable diseases in a true light. For example, with regard to cancer, the benefit of research will accrue mainly to future generations and they should be made to bear the burden of loans from which this research is financed. As to tuberculosis it should be a commonplace that what we need is education, appropriate legislation, workers adequately remunerated, and buildings which would be required for only a term of years that could be estimated; then the white disease could be made as rare as rabies for generations that would gladly pay for such freedom.

London, W.2. JOHN MACLEAN.

ACUTE POLIOMYELITIS

SIR,—The following two cases of acute anterior poliomyelitis illustrate some important diagnostic points.

CASE 1.—A boy, aged 6, was admitted with a history of vomiting three days earlier from which he had recovered and returned to school two days earlier, the vomiting recommencing the day before he was seen. On examination he was very confused, with slight neck rigidity and brisk reflexes; the bladder was distended half-way to the umbilicus. A provisional diagnosis of poliomyelitis was made, and was confirmed the next day by the appearance of unilateral facial weakness of nuclear origin, and by the disappearance of all other symptoms. The cerebrospinal fluid (C.S.F.) contained 10 red blood-cells and 55 white cells (40 lymphocytes, 15 polymorphs) per c.mm.; there was 85 mg. protein per c.cm.

CASE 2.—A boy, aged 3, developed listlessness, which continued for three days. After being apparently recovered for two days he developed vomiting, pains in the legs, and drowsiness. On examination six days after the initial symptoms, his general condition was satisfactory. He had a bladder distended to the level of the umbilicus. The next day facial palsy of lower motor-neurone type appeared. The C.S.F., obtained with some difficulty, contained 400 red blood-cells and 10 lymphocytes per c.mm., and 45 mg. protein per c.cm.

From discussion with other doctors it appears that vomiting is common as a symptom of the initial illness, sometimes clearing up temporarily. In both these children the distension of the bladder had been missed, presumably because the child's crying made the abdomen less easy to palpate. American authorities find that bladder involvement occurs in 40% of cases of poliomyelitis. In fact during this epidemic retention of urine (sometimes combined with an up-going plantar response) is highly suggestive of acute anterior poliomyelitis. This does not appear to be widely appreciated, and as it may be a very useful early diagnostic sign it seems worth while to draw attention to it.

Children's Department, Central
Middlesex County Hospital,
London. RONALD C. MAC KEITH.

SIR,—In view of the steadily increasing incidence of poliomyelitis and the lack of any specific treatment in the acute phase of the disease, I should like again to emphasise the apparent value of intensive sulphonamide therapy when applied early in the illness.

The following case was lately seen by me in consultation.

An R.A.F. groundsman, aged 19, was at work up to 5 P.M. on Saturday though he had had severe headache with considerable malaise since midday. He went to bed when relieved of duty, but had a restless night, with severe pains in the neck, back, and limbs. He reported sick with severe headache the next morning, when his temperature was 102°F. He was admitted to a fever hospital on Sunday evening. His temperature was then 102·4°F; he had headache, and pains in the back and limbs; neck rigidity was present. Lumbar puncture showed the cerebrospinal fluid to be at 200 mm. pressure; protein and globulin were increased, and the cells numbered 84 per c.mm. (polymorphs 40%, lymphocytes 60%). When seen by me on Monday morning his temperature was still 102°F; neck rigidity was pronounced, with pain and tenderness in the muscles of neck and back; tendon reflexes in the upper limbs were absent; the abdominal reflexes were absent on the left side and greatly reduced on the right side; there was slight weakness of the left lower limb and the left knee-jerk was absent. There was also considerable paresis of the muscles of the back, the patient being hardly able to raise himself to the sitting position; this had developed in the previous twelve hours.

On admission to hospital the patient had been given sulphamerazine 2 g. by mouth, followed by 1 g. four-hourly. He was now given soluble sulphathiazole 4 g. intravenously, followed at twelve-hourly intervals by 3 g. intravenously; the sulphamerazine by mouth was continued. Seventy-two hours later the fever had completely subsided and there was no further increase in the paresis; the intravenous sulphonamide was now stopped. Ten days after the onset of the illness the patient had recovered almost completely.

As Dr. S. Wray and I[1] have already pointed out, intensive intravenous therapy assures a high concentration of sulphonamide in the blood, whence, it is suggested, it diffuses in effective quantities to the anterior-horn cells and cuts short the infection. The response in this case is similar to those in the previous series and well warrants a further trial of the method. There is no need to stress the necessity of giving fluids and alkalis freely, and of a careful watch on the cytology of the blood and frequent examination of the urine.

Duchy House Clinic, Harrogate. SINCLAIR MILLER.

EMOTIONAL ASPECTS OF SKIN DISEASE

SIR,—Dr. Gladstone Robertson's article (July 26) must call to mind the experiences of many of us in the Services. The skin, among other organs, suffered frequently from the infidelity of the wife of the Serviceman abroad, whose anger and fear could not be expressed naturally because of the difficulty of traversing the distance between himself and his wife.

Urticarias and eczemas were frequent; but the most curious of the emotional skin reactions was impetigo of the back of the neck. I saw four cases, the victims, though not necessarily blameless ones, of an unfaithful wife. All harboured an intense sense of grievance against the circumstances that had allowed this to happen and resented their powerlessness to do anything about, it.

Queen Elizabeth Hospital, Birmingham. JOHN HAMBLING.

SIR,—Dr. Gladstone Robertson is to be congratulated on his successful application of psychotherapeutic methods to the treatment of skin conditions. Although details of the personalities discussed are not given, they appear to approximate, broadly speaking, to the typical personalities of seborrhœic-dermatitis patients—viz., the socially inadequate obsessionals. Such patients have always had difficulties in their social relationships, owing to their being reserved and retiring, with deep-seated feelings of inferiority and inadequacy. They are unaggressive, and at the same time compulsively overconscientious perfectionists, with intense guilt feelings which cause them to fear punishment and insecurity.

Dr. Robertson has rightly described the precipitating factors, which are associated with self-esteem and social status; the skin condition being a protest against the treatment meted out to him by his fellows, a self-imposed punishment, or the evasion of a situation intolerable to him.

The direct attack on the psychological aspect of illness on a purely intellectual level will, of cou create havoc in such poorly integrated personali Hence the flare-up of the condition and the retreat of the patient to his own defences. Only by gaining a g positive transference can his anxieties and aggressi be "piecemeal" abreacted, and so experienced on emotional level. This in many cases leads to a disapp ance of the skin condition, but in order to prevent re he must readjust his emotional life in relation to social milieu. This requires, of course, more prol treatment.

Netherne Hospital, Coulsdon, Surrey. J. SLORACH

INJECTABLE CRYSTALLINE HORMONES

SIR,—There are several drawbacks to the s cutaneous implantation of pellets of crystalline horm It involves a surgical operation, which, however cannot be repeated frequently and therefore necess the use of large pellets which will sometimes con hundreds of milligrammes of the hormone; the is not constant, as the rate of absorption depends on surface area, size, shape, and degree of compressio the pellet; the amount absorbed decreases in the c of time with diminution in size and alteration in shap the pellet; sterilisation by heat destroys the compo and local infection sometimes follows implantation.

These difficulties have stimulated the search for suitable methods. Freed and Greenhill[1] found that suspensions of crystalline œstrone in aqueous m are more effective therapeutically than oily solut of the hormone. Miescher et al.[2] demonstrated feasibility of injecting a crystalline suspension of hormones. Méier et al.[3] found that the injection of large single dose of an oily solution of desoxycort *into an adrenalectomised dog* did not give a prop tionately longer period of action than the injectio smaller doses. Thus an adrenalectomised dog weig 10 kg. can be maintained in a state of health with single daily injection of 1 mg. of the hormone, whereas single injection of 100 mg. is effective for only nine da On the other hand, a large single dose of cryst. desoxycortone administered in aqueous suspension d act for a considerably longer period. Up to a certa limit the daily maintenance dose of this suspens increases in proportion to the size of the dose injected.

Meier et al. also showed that the action can be pr longed by increasing the size of the suspended crys *A wide-bore needle is necessary for the injection* of su suspensions: in fact, we had difficulty in filling th syringe and injecting the suspension even throug wide-bore needle. To overcome this difficulty, suggest the use of an *absolute* solution of crystal hormones to form a subcutaneous depot of crystals the site of injection. We adopted the method devel by Rappaport[4] for prolonging the action of injectio 'Anæsthesin.' The organic solvent used is a 5 solution of urethane in water to which 10–20% of m acetamide has been added. The crystalline horm dissolve in the organic solvent, preferably under g heating, but remain in unstable equilibrium, so th addition of a small amount of water causes precipit of the crystalline hormones. When the horm dissolved in urethane come in contact with the s cutaneous fluids (an aqueous solution) at the site of inj *tion they are immediately precipitated.* The solut rapidly absorbed, while the insoluble hormone crys remain at the site of injection. We have used th method for injecting desoxycortone, testosterone, p gesterone, and œstrone. The solution can be inject with a no. 20 needle.

Through the courtesy of Dr. S. Btesh, chief of t *medical* service, *Government Hospital*, Tel-Avi were able to test the efficacy of 30 mg. of desoxycort dissolved in urethane and methyl acetamide injec subcutaneously in a case of Addison's disease. T site of injection was first infiltrated with 2–3 c.cm. of 1% procaine, and 3 min. later the hormone solution ed at the same place, thus avoiding the temporary pain and producing an additional depot of water ie precipitation of the hormone crystals. (More ly we have mixed procaine with the hormone on in the ampoule.) The maintenance dose of this it, during the year before he came under our vation, had been 5 mg. of an oily solution of ycortone every 4 or 5 days. After the administra- of 30 mg. of desoxycortone in urethane, the treat- could be stopped for five weeks, during which time atient felt perfectly well.

RAVENOUS INFUSIONS AND MASTOIDITIS

,—A good deal has been heard recently about the dence of gastro-enteritis and mastoiditis in infants, he coexistence of these diseases has been established arge number of cases, posing very difficult problems gnosis and treatment.

iave been pathologist to a children's hospital of , 100 beds for the last eighteen years, and during time I have seen numerous cases of gastro-enteritis iave performed post-mortem examinations on many em. In the early years nursing management was ss efficient than it now is; yet except at times of mic, we had no such terrifying succession of deaths s now become almost a commonplace.

is true that in the post-mortem examinations of days we did not look for mastoid disease in the ice of external signs; but in the vast majority of cases gastro-enteritis alone was the cause of death espiratory infection was only occasionally present. exact opposite is now the case; and my personal is that the mastoiditis is an indirect result of nt-day treatment, the villain of the piece being the venous saline drip fixed up by enthusiastic house- and necessitating the exposure and handling of the it. The result is either a directly occurring broncho- monia, or the indirect sequence of embarrassed lation leading to respiratory embarrassment and tion, with consequent mastoiditis in either case.

believe that the old subcutaneous saline was much harmful, and I think the intravenous drip should ised, if at all, far more conservatively and with itely more skill and judgment.

A HYGIENIC FORK

R,—The table-fork of today is the outcome of much rience and experiment, and the number of its prongs ld not be lightly altered. As an indication of the culties surrounding this problem, we may recall Miss Matty's *Cranford* friend, unexpectedly faced old-fashioned two-pronged forks, felt compelled ave her delicate young peas untasted on the side of plate.

shey Heath, Herts. F. CAMPBELL ROSE.

BDOMINAL TUBERCULOSIS TREATED WITH CALCIFEROL

R,—In connexion with recent reports of the success- use of calciferol in some forms of tuberculosis, the wing case appears to be worth recording.

n unmarried woman, aged 23, began to have recurrent cks of abdominal pain and vomiting in April, 1946. September she was seen at the South London Hospital sent to the Schiff Home, Cobham; she was noted to have grade pyrexia and an ill-defined abdominal mass.

iss C. M. Stacey performed a laparotomy on Oct. 2. peritoneum was studded with tubercles, and the viscera so matted together that it was impossible to explore pelvis or abdomen; biopsy of one of the lesions showed appearances of tuberculosis.

n Oct. 5 she was put on calciferol 50,000 units thrice y. Her general condition soon began to improve, but Nov. 21 the drug was temporarily discontinued as the m calcium had risen to 13·2 mg. per 100 ml.; her abdomen become much softer, and she had no symptoms of calciferol overdosage. Treatment was resumed on Dec. 10 with a dosage of 50,000 units once a day; this was continued until May, 1947.

Apart from a brief attack of abdominal pain and vomiting at the beginning of December, she made steady progress; by the end of February she was up and about all day, afebrile and symptom-free. Nothing abnormal could be felt in the abdomen, and she was discharged apparently well at the end of March. Early in June she was still very well, and free from abdominal signs.

A rapid recovery was not expected in this case of plastic tuberculous peritonitis; and calciferol may well have exerted a favourable influence.

I wish to thank Miss Stacey and Dr. G. S. Yeoh for permission to publish this report.

St. Thomas's Hospital, London, S.E.1. ROBERT BOWERS.

EX-BORSTAL MEN IN THE FORCES

SIR,—The last paragraph of your account (Aug. 9) of the Prison Commissioners' report caught my eye. I have not yet read the report itself, but a question sprang to my mind.

Has any satisfactory follow-up been made on these thousands of young men who, discharged from Borstal, have gone into the Services? It is entirely as it should be that they can rehabilitate themselves without any stigma from their past mistakes. It seems to be a vital matter that we should know how many do and how many do not succeed in becoming adjusted soldiers and citizens. Further, we need to know why any failures occur.

The careful methods of selection and sorting for review of sentences of deserters in B.A.O.R. showed much promise, and we should be able along such lines to understand more of the personal and social factors involved in the prognosis of delinquency.

It is not merely a concern for the morale of the Forces in peace-time, nor for a check on Borstal results and prognoses which prompts this question. We have surely to our hand a unique opportunity of testing our understanding and techniques in dealing with adolescent delinquency. The provision of suitable investigators by the commissioners and the Home Office should pay a handsome dividend.

London, W.1. J. R. REES.

PLASTER TECHNIQUE IN INTRAVENOUS INFUSION

SIR,—Valuable time is often lost in blood-transfusions or saline infusions by interruption of the intravenous flow. Occasionally this is caused by venous thrombosis, but more often it is due to sudden interference with the position of the intravenous cannula or tubing during some form of nursing procedure. Such interruptions can be reduced by substituting for the usual back splint and crêpe bandage a light plaster, as follows:

The vein is exposed in the usual way near the medial malleolus, and the infusion is started.

The rubber tubing is fastened to the dorsum of the foot with adhesive plaster so that it passes between the great and second toes.

A gauze dressing is then applied to the site of incision, and the ankle is placed in the neutral position.

A 6 in. plaster bandage is next so applied as to form a light unprotected plaster boot. In most cases one bandage is sufficient. If more bandages are necessary, care should be taken to avoid making the plaster too heavy. Within twenty minutes the plaster is sufficiently set to permit unrestricted movement, and the leg can now be replaced under the bed-clothes.

This technique was first used on patients with much restlessness following operation for intracranial complications of mastoiditis, but the method proved so successful that it was extended to all patients requiring intravenous infusion. The advantages of this technique are as follows: (1) the lesser restriction of the patient's movements spares him the discomfort of keeping the limb in a fixed position; (2) it facilitates nursing; and (3) it reduces the incidence of pressure points on the back and ankles.

There is as yet no statistical evidence that this technique reduces the incidence of embolism or hypostatic pneumonia. It seems reasonable, however, to assume on basic surgical principles that the increased facility for movement on the part of the patient will reduce the chances of thrombosis and chest complications as compared with patients immobilised with a back splint.

London, N.W.10. **DENYS E. HOWELLS.**

Dr. P. J. SMITH, who appealed in our columns last May for textbooks for medical "displaced persons," writes: "I wish to thank each of my colleagues who so kindly sent medical literature for the use of D.P. doctors. Should anyone not have received a personal acknowledgment I should be glad to hear from him." Dr. Smith's address is now Drimoleague, co. Cork.

Public Health

ADMINISTRATIVE MEASURES AGAINST POLIOMYELITIS

CONFERENCE IN LONDON

A SPECIAL meeting of some eighty medical officers of health from the home counties, or their representatives, was held at the Central Public Health Laboratory, Colindale, on Aug. 8, to discuss administrative measures during the present epidemic of poliomyelitis. Medical officers of the Ministry of Health attended.

It was stated that at the present rate of notification some 5000 notified cases might be expected before the end of the year; this was far in excess of the incidence in any previous year since the disease became notifiable in 1912 (following, as was pointed out, a high incidence in 1911, which was also a year with a hot dry summer). About a third of the notified cases admitted to hospital this year were not confirmed as poliomyelitis; and although the proportion of patients with cranial-nerve involvement was probably higher than usual, severely ill cases were not very numerous. The highest incidence was in those aged between 8 and 16 years, with about equal numbers in children below this age and in young adults.

PRECAUTIONARY STEPS

The following measures were generally considered acceptable:

Swimming-baths and paddling-pools.—Swimming-baths should not be closed unless there is some definite indication that cases have been or may be infected there. The number of children admitted on any day should be restricted, and the children should be advised to stay for only a short period in the baths. Overcrowding is probably a more important factor than infection of the water in swimming-baths.

It has been found that the poliomyelitis virus is destroyed by exposure to 0·2 parts of free chlorine per million for ten minutes.

Hired bathing-suits and towels should be washed and laundered between use, and the floors of changing-huts should be washed out and mopped with a disinfectant solution.

Fresh-water paddling-pools in areas where cases have occurred should be drained so as to discourage the congregation of young children; and a bacteriological check might be kept on natural bathing-pools to see that they do not become heavily contaminated. There is no risk from river bathing unless sewage effluent is entering the river nearby.

Schools and nurseries.—Schools should reopen on the normal dates unless there are special reasons to the contrary. Some attempt might be made to restrict attendance of intimate contacts of cases for three weeks after the onset of illness.

In regard to nursery schools and day-nurseries, on the occurrence of the first case all parents should be informed, and if there is a second case the nursery should be closed. The chances of spread of the virus are likely to be greater among young children playing in close contact in nurseries than the ordinary schools.

Cinemas.—Closure of Saturday-morning cinema shows for children is not recommended: they should not be closed it is certain that the children will not go to a neighbouring cinema and so cause the overcrowding which it is desired to avoid.

Household contacts.—The parents of children and adolescents who have been in contact with a case should be warned to keep them as far as possible from other children and young people.

Generally speaking, no action should be taken to [illegible] adult contacts, but those who are food-handlers should be warned to be particularly careful of personal hygiene. If a contact food-handler becomes ill an attempt should be made to persuade him and his employer to arrange that he does not handle food for at least a fortnight.

Flies.—Although there is no evidence that the fly is playing a part in the spread of infection in the present outbreak, efforts should be made to minimise the fly nuisance as a general public-health measure. Salvage food-bins should have tight-fitting lids and should be emptied frequently.

Fruit, milk, and other foods.—Fresh fruit and milk have been suspected in the past as possible vehicles for the spread of poliomyelitis, and suitable precautions may be taken—e.g., by washing fruit and peeling the skins before eating, and by pasteurising or boiling raw milk.

Tonsillectomies, extraction of teeth, and E.N.T. operations should be avoided in areas where cases are occurring.

MODE OF SPREAD

Dr. ROBERT CRUICKSHANK, director of the Central Public Health Laboratory, mentioned that the virus was demonstrable in the oropharynx of 30–50% of cases for some days before and after onset of typical symptoms; and it persisted in the stools of half the cases for 3–4 weeks after onset. Although the present tendency in America, as represented by Sabin[1] was to stress the intestinal mode of spread, epidemiological evidence suggested that the respiratory route was perhaps more common and that patients may be most infectious in the prodromal stage. He asked clinical colleagues to record particularly any history of nasopharyngitis at this early stage.

The great rarity of infection among those nursing paralytic poliomyelitis, despite the presence of virus in patients' fæces, was in contrast to the findings in typhoid and dysentery. Respiratory infections might spread in high summer, as witness the present prevalence of measles. Infected dust might be a factor, although outbreaks in the U.S.A. had occurred in wet as well as dry seasons. Another epidemiological feature of poliomyelitis was that outbreaks did not recur in the same area in consecutive years, which suggested a widespread latent immunisation with the virus.

CLINICAL FEATURES

Dr. W. H. KELLEHER described some of the clinical features of the cases admitted to the Western Hospital, L.C.C. Only a quarter of the cases were under 5 years of age, the remainder being in patients of up to 32 years. As an example of the protean nature of the disease, of three adolescent girls admitted from the same institution, one had no paralytic symptoms but showed evidence of meningeal irritation and changes in the cerebrospinal fluid; the second had polioencephalitis with [illegible] peripheral paralysis; while in the third only one group of muscles was affected. Lumbar puncture might be a useful diagnostic aid in doubtful or abortive cases. It was suggested that cases of poliomyelitis should be brought together under expert nursing and medical care; in particular the handling of bulbar cases calls for experienced staff. Attention was drawn to the possible occurrence of anoxæmia from bulbar paralysis simula

phalitis.[2] There was no shortage of iron lungs; any cal officer requiring one in a hurry should get in h with the London Emergency Bed Service (Tel.: arch 8515). Respirators not in use should be over- ed and made serviceable. There should be close on between physician and orthopædic surgeon so paralysed patients can have remedial treatment as as possible. The supplies division of the Ministry Iealth had been asked to make available through regional organisation a supply of bed-cradles, ibly to be lent out for use by patients in their own es.

PATHOLOGICAL MATERIAL

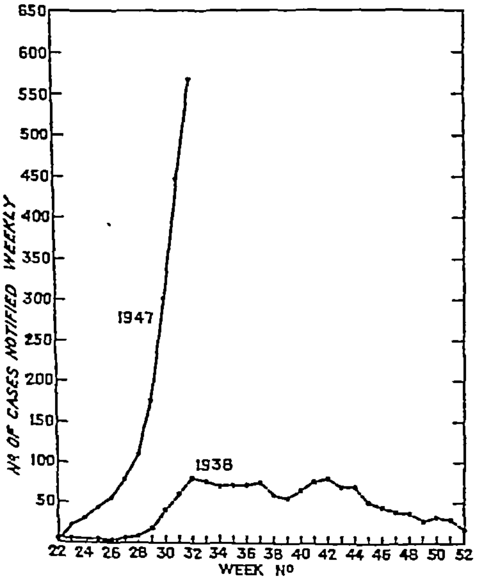
r. F. O. MacCallum, of the Virus Reference Labora- , Colindale, had been receiving brain and cord tissue)% glycerol saline from different parts of the country. was also collecting samples of serum from acute and valescent cases for assay of neutralising antibody nst the Lansing strain which had been adapted to ents. He wished to discourage clinical colleagues from ling further specimens of cerebrospinal fluid, fæces, rine, except by special arrangement.

PRESS PUBLICITY

was suggested that medical officers of health should personally with the local press, supplying them with factual information as was available. The Ministry Health has tried to guide the national press, parti- rly in the avoidance of alarming or sensational ements.

Poliomyelitis and Polioencephalitis

he number of cases of poliomyelitis notified in gland and Wales during the week ended Aug. 9 s 568. This is an increase of about 27% on the figure the previous week (448); and it is a considerably maller proportional increase than the 50% recorded for ar successive weeks before that. Increases in noti- ations were recorded in the following county areas gures for the previous week are shown in parentheses): ncs 71 (36); London 84 (53); Middlesex 35 (20); arwick 23 (13); and Kent 21 (13). Decreases were corded in Yorks, West Riding. 57 (70); Yorks, East lding, 5 (16); Durham 36 (45); and Surrey 24 (32).



Notifications of polioencephalitis were 56, compared ith 39 the previous week. For the four weeks ended July 5, 12, 19, and 26 notifications numbered 9, 16, 16, and 34 respectively.

Infectious Disease in England and Wales

WEEK ENDED AUG. 9

Notifications.—Smallpox, 0; scarlet fever, 680; whooping-cough, 1508; diphtheria, 138; paratyphoid, 7; typhoid, 9; measles (excluding rubella), 5488; pneumonia (primary or influenzal), 225; cerebrospinal fever, 66; poliomyelitis, 568; polioencephalitis, 56; encephalitis lethargica, 1; dysentery, 78; puerperal pyrexia, 103; ophthalmia neonatorum, 66; relapsing fever, 1. No case of cholera, plague, or typhus was notified during the week.

Deaths.—In 126 great towns there were no deaths from enteric fever or scarlet fever, 1 (0) from diphtheria, 4 (0) from measles, 7 (0) from whooping-cough, 61 (5) from diarrhœa and enteritis under two years, and 3 (0) from influenza. The figures in parentheses are those for London itself.

The number of stillbirths notified during the week was 215 (corresponding to a rate of 25 per thousand total births), including 25 in London.

Parliament

ON THE FLOOR OF THE HOUSE

The House has adjourned until Oct. 20 and M.P.'s and Ministers, Government and Opposition, go back to their homes. Their morale will improve after a few weeks, for the strain all have been through has had its effects.

At the last sittings of Parliament, when extension of powers under the Supplies and Services Act was considered, the Commons took the debate feverishly because it is the chamber in which political differences and controversies are most acute. The House of Lords, where the Opposition is in overwhelming strength, dealt with the matter more calmly but indicated their view of the national situation by deciding to adjourn only until Sept. 9, when they will consider whether any urgent matters have arisen which require their attention. The difference is merely one of attitude; for it is competent for the Speaker to call the House of Commons together at any time should the Government think it necessary.

During the week the House had the opportunity of seeing an unusual power of the Commons being exercised. The Lord President of the Council and Leader of the House moved, and the House agreed, that two witnesses who had refused to answer questions put to them by the Select Committee of Privileges should be summoned to the Bar of the House "forthwith." The ritual was impressive. The Sergeant-at-Arms, on command of the Speaker, rose from his place, marched to the table before the Speaker's chair and shouldered the Mace. Then turning he returned to the Bar of the House, which is a mark on the floor of the chamber farthest from the Speaker's chair, and went outside to where the witnesses were waiting. These two gentlemen then marched in, followed by the Mace-bearer, and bowing three times to the Speaker, stood at the Bar to answer the Speaker's questions. Having apologised for their previous refusal they then gave their answers to the House as a whole and retired. The House decided, as soon as they had withdrawn, that no further action was necessary. What could have been done is a matter of speculation. But the House of Commons can decree its own penalties and could enforce severe punishment including imprisonment did it think fit.

The last day was nominally devoted to the motion for the adjournment, though the arguments put forward were more appropriate to the State of the Nation discussions than to those of dates and times. But at 2.15 this, too, came to an end, the Opposition not resisting the closure, and the final formalities were completed with a tail of adjournment debates on a variety of topics on which members would have shown more enthusiasm if they had been less fatigued.

During these last days some interesting facts about the Armed Services emerged. There are in these

THE DOCTOR'S MISSION*

J. R. LEARMONTH

E., Ch.M. Glasg., Hon. M.D. Oslo, F.R C.S.E., F.R.S.E.

JS PROFESSOR OF CLINICAL SURGERY AND PROFESSOR OF SURGERY, UNIVERSITY OF EDINBURGH

once you must abandon any idea that you are to ne your work to medical practice. My educationist , A. N. Whitehead, has laid it down that, " the life Ian is founded on technology, science, art, and ion. All four are interconnected and issue from his mentality." It is with the life of Man that your will lie. In the community of your choice you will oncerned with the care of the sick, and with the ention of illness, both physical and mental: but lieve that your experience in the university has l you to help to promote that part of the total life Ian which is founded on science, and it is my con-ion that your work should include an attempt to aint the members of your community with the der aspects and broader values of scientific work, so to secure for science a place in the foundations uman activity and of human conduct. I say *a* place sedly, because it would be wrong, and misleading, xhort you to claim for science a disproportionate e in the pattern of life ; so incomplete is our present vledge of human relationships that he would be a man who essayed to define the relative importance cience, or of technology, or of art, or of religion. h is to be sought in all four.

predict that you can be only partly successful in r attempts, because success cannot be achieved until system of education in schools and in universities ures that every citizen shall have some knowledge the sciences, and particularly of biology. This ientation in education will take at least one genera- and probably longer before it is completed. Until ı, the importance of scientific subjects which a scientious and intelligent student may need several rs to grasp cannot be explained to an individual over nner-table, or to a community at an evening meeting. il then, often you must be expositors, although the rable rôle for a medical man is that of commentator. il then, any health service cannot be completely essful, because it will be operating in a community which the citizens lack the fundamental knowledge nake full use of it.

APPROACH TO THE OBJECTIVE

Inlike certain other branches of science, fortunately licine, from which you will draw most of your strations, is not at intervals faced with the moral blem of assessing the proportions of good and bad ch may accrue out of knowledge gained under ormal conditions such as those of war. In medicine, added knowledge is ultimately of direct benefit to nkind. Yet it would be unfortunate if this yard-k of " direct benefit " were to be the only one applied the public to assessing work in science, the more so ause for some time to come the laity will remain ditioned to regard scientific achievements more otionally than dispassionately. Our professional aims doctors may make you more agreeable pleaders: this should not deter you from the strategic educa-nal objective, that—if its best minds are to be given scope—a nation cannot and must not attempt to ne any " end " to the work of its scientists. Happily, conclusion of the war freed science from the rigid essity of confining itself to the exploration of problems immediate military applicability, and restored its e function of adding to the body of knowledge. The plication to surgery of what should be the ideal yardstick was aptly crystallised by the late Dr. Harvey Cushing, himself one of the most expert surgical craftsmen of all time, in the remark that he looked forward to a day when some university would be farseeing enough to appoint a professor of surgery who had been born without hands.

How is this strategic objective to be approached during your professional lives? You must first realise that during *your* lifetime those to be educated will include the adult members of the population, and that you cannot be their teachers until you have lived for a while in the outside world, and paid heed to what goes on around you ; not until then can you hope to be acceptable to your fellow citizens as interpreters of scientific matters. And you must keep abreast of all that may modify your apostolic mission—new ideas, new armamentarium, new methods, approaching these with open minds and with critical interest. Some of the universities are well on the way to providing you with opportunities for so doing ; you can never consider your own education to be complete ; although graduates you must remain students.

How are you to begin this educational work? One way of beginning—and to my mind a most attractive way—is to present science, including medical science, as a branch of learning which offers to those who follow it exciting opportunities for doing things which have never been done before ; opportunities which are not affected by belief in this creed or that ; opportunities which have the advantage—so desirable in our disturbed world—of not being limited by any geographical boundary ; opportunities which can be restricted to the narrowest of objectives or on occasion expanded to the broadest ; opportunities in which the method is primary, the objective secondary.

ATTITUDE OF THE PUBLIC

You will have difficulties in such educational work: and these will be both general and particular. I may remind you of the difficulty of explaining to the laity that progress in science, and particularly in medical science, is both continuous and episodic, episodic progress depending on the genius of men and of women and on the possibilities of putting promising therapeutic agents to properly controlled clinical trial. On the other hand, one of the aspects of scientific work which bewilders unscientific people is the speed at which progress is occasionally made. You must expound advances against the background of the age in which they occur : in its time the invention of the wheel was more revolutionary than was the more recent invention of television. At first progress could be summed up every century or so ; then every decade ; but nowadays it may be every year, or even every month. Compare the medical progress made in the last century with that made in the preceding nineteen centuries, and with the speed at which men's minds have been attuned to accept that progress ; in this year of the centenary of the discovery of the anæsthetic property of chloroform in our own university, it is still disconcerting to recall how slow was its acceptance. Moreover some advances have an emotional appeal, which is more attractive to human nature, and therefore a more tempting educational starting-point than others less spectacular but more fundamental. For a thousand citizens who understand that penicillin saves many lives in each year, you would have difficulty in finding one who realises that the addition of chlorine to drinking-water makes it, every day, safe for millions : yet it is of supreme importance that your public grasp this to them difficult perspective. These are some of the perplexities which are common to all members of the public, whatever their income, whatever their previous non-scientific education.

As to particular difficulties, the experience of an older man may perhaps help you to overcome them, not by

Notes and News

REPLACING THE RETROVERTED UTERUS

At a meeting of the North of England Obstetrical and Gynæcological Society in Liverpool on July 4, Prof. T. N. A. Jeffcoate described a simple method of replacing the retroverted uterus by manipulation with a Hodge pessary; the method does not call for the usual bimanual replacement before insertion of the pessary. With the patient in the left lateral position the Hodge pessary is inserted and allowed to take up its own position; the upper rim comes to lie in the anterior fornix and the lower bar projects beyond the introitus. One finger is then inserted behind the lower bar, through the pessary and in front of the upper rim, which is pushed against the anterior aspect of the cervix. The cervix is thus deflected backwards and the body begins to rotate forwards. Ultimately the upper rim slips past the cervix into the posterior fornix. By this time the retroversion is nearly always corrected, but sometimes not completely, the uterus lying with its axis vertical. In such cases the upper end of the pessary is pushed firmly against the posterior vaginal wall and the posterior fornix repeatedly "stroked" backwards and slightly downwards with the pessary. At the same time the lower end of the pessary comes to lie at a higher level. Thus the cervix is levered backwards and the fundus comes forwards; and the pessary is automatically left in its correct position.

STAFF FOR CARE OF THE OLD

In the West Middlesex Hospital, care of old people has reached a very high level (see *Lancet*, 1947, i, 760). The geriatric wards, under Dr. Marjory Warren, take 180 patients all of whom are actively treated and reabled, as far as possible, many of them being discharged on recovery or improvement. The Middlesex County Council are anxious to encourage this work, and are therefore appointing a senior and a junior resident house officer to work with Dr. Warren. The example of the West Middlesex deserves study by all authorities and doctors responsible for the care of the old in hospitals and institutions.

FOR PSYCHIATRIC SOCIAL WORKERS

Three pamphlets—on war-damaged children, foster-home placement for difficult children, and interviews with parents in a child-guidance clinic [1]—have just been published by the Association of Psychiatric Social Workers. These nicely produced and informative little volumes are the outriders of a series on various aspects of psychiatric social work. Written in a straightforward pleasant style, they set out material which may well be as useful to the family doctor as to the social worker.

University of Birmingham

The title of reader in the university has been conferred on Dr. W. Trevor Cooke, first assistant in the department of medicine.

University of Sheffield

The offices of the dean of the faculty of medicine are now at 358, Mushroom Lane, Sheffield, 10.

University of Durham

On Thursday, Sept. 25, at 5 P.M., at the Royal Victoria Infirmary, Newcastle-on-Tyne, Dr. Frank H. Lahey, of Boston, Mass., will deliver the second Rutherford Morison lecture. He will speak on Thyrotoxicosis, Thyroidectomy, Thiouracil.

University of St. Andrews

Dr. G. H. Bell, lecturer in physiology in the University of Glasgow, has been appointed to the chair of physiology in the university.

Dr. Bell graduated B.SC. in the university of Glasgow in 1929 and M.B. with honours the following year. After holding a house-appointment at the Royal Hospital for Sick Children in Glasgow, he became assistant in the department of physiology in the university. A period as lecturer in physiology in the University of Bristol followed, till he returned to Glasgow to take up the same position there. In 1943 he was awarded the gold medal for his M.D. thesis, and in the same year he published the 3rd edition of his *Experimental Physiology*. Dr. Bell has also written on capillary fragility and hæmoglobinometry, and he has devised (with E. Guthmann) a simple photoelectric absorptiometer.

Royal College of Surgeons of England

The following were successful in the recent pass fellowship examination:

Ministry of Health

Mr. J. E. Pater has been appointed an under-secretary the Ministry.

Mr. Harold Davis, PH.D., F.R.I.C., who has been pharmacist at University College Hospital since 19 been appointed as chief pharmacist to the Ministry.

Poliomyelitis in the United States

The U.S. Public Health Service in Washington is by B.U.P. as reporting that the danger of a polio epidemic is diminishing; cases reported in a typical in July were only half the five-year average, and the number of cases reported so far this year is only 1675, co with the five-year average of 2048 and last year's 3256.

N.A.P.T. Scholarships

The National Association for the Prevention of Tuber is to offer six scholarships this year: two (value £1 to registered doctors in the Colonial Medical Service; (value £100 each) to medical graduates of native schools the British Colonies; and two (value £80 each) to male nurses, health visitors, or other members of colonial departments. Applications should be submitted through Colonial medical departments to reach the Colonial not later than Aug. 31.

A refresher course in pathology and bacteriology will held in Oxford between Sept. 23 and 26.

Training in Child Care

The Home Office has appointed a Central Training Co in Child Care to organise courses and select candidates work among children who have been deprived of a home life. The medical members of the new council Dr. C. Fraser Brockington and Prof. Alan Moncrieff.

University courses, the first to begin this year, are to held for boarding-out-officers who will supervise chil placed in foster homes. For these applications are in from women between 21 and 40 with a university degree a social-science diploma. There are also to be courses house mothers, and for these applications are invited women aged 18 to 35 with a good general education and "deep interest in providing a home background for children Grants will be available towards fees and maintenance

Regional Boards' Appointments

The following appointments have been made by the *Regional Hospital Board:* senior administrative officer, Dr. G. C. Williams (M.O.H., Oxford city); secretary Mr. George Watts, F.H.A. (secretary, Berks, Bucks Oxon Regional Hospitals Council of the Nuffield Prov Hospitals Trust).

The *Welsh Regional Hospitals Board* is reported by *Manchester Guardian* (Aug. 13) as having received 51 appli tions for the post of senior administrative medical those short-listed are Dr. A. T. Jones (medical officer Welsh Board of Health, Cardiff), Dr. T. L. Hughes Middlesbrough), Dr. G. Rocyn Jones (M.O.H., Monmouth and Dr. J. Greenwood Wilson (M.O.H., Cardiff). Of 17 applied for the post of secretary, 4 have been short-listed The appointments will be made on Sept. 9.

The King of Norway has conferred the decoration knight 1st class of the Royal Norwegian order of St. O on Mr. C. Bowdler-Henry "in recognition of services ren during the war." In 1942 Mr. Bowdler-Henry was appo honorary consulting oral surgeon to the Royal Norw Forces in the United Kingdom and to the Norwegian Mi of Social Welfare.

TWO ESSAYS ON
THE PRACTICE OF MEDICINE

ROBERT PLATT
M.D. Sheff., F.R.C.P.
ROFESSOR OF MEDICINE, MANCHESTER UNIVERSITY

has seemed to me for a long time that good doctors from bad ones in two major respects. The time they e to history-taking and their ability to interpret ory correctly is the first. The second is their ability mulate a plan of treatment. I have written down houghts on these two subjects in the form of two essays.

On History-taking

now that I am not alone in thinking that history-g is the greatest art in medicine. Generations of al teachers have acknowledged its importance and tried to pass on the art to their pupils. Yet there are ers, doctors, and students who still fail to appreciate ajor place in diagnosis.

ny physicians select for their ward teaching cases good physical signs and reject or pass over the with a good history and no signs at all. In the atient department they allot cases to their clinical s so that in effect the clerks are doing the same in department as they do in the wards. In this way it ssible for a medical student to go through his whole e without ever hearing a patient interrogated itio by an expert clinician.

students have to understand that they come to outpatient department to learn the art of consulta- and above all to hear me taking case-histories. the history has been taken, we discuss the provi- l or possible diagnosis *before* examining the patient. ere are some who may regard this procedure with ishment if not with horror, but it is really only llustration of the process whereby all good doctors e at a diagnosis. It is quite impossible for an ligent physician to take a history without diagnostic ibilities being presented to his mind. Far more akes are made by putting too much significance upon tful physical signs and neglecting the clear indica- s of the history than by the opposite process. After examination we reconsider the diagnosis in the light ur further findings.

ere is a special reason why the value of history g needs to be emphasised today. We are embarking a National Health Service in which laboratory ities will be freely available for the first time to nary patients in general practice. The practitioner ometimes under the illusion that the consultant's k is relatively easy—he has the resources of the ratory and the X-ray department at his disposal and only to set the machine in operation for the correct nosis to be produced for him. The consultant of erience knows full well that it is not so. He knows wasteful and misleading the ancillary services may e if due care has not been given to the initial exami- on of the patient and above all to the history. If ratory and X-ray services are to be intelligently l, history-taking must become more, not less, ortant and it is a task which in difficult cases can er be delegated.

AN INQUIRY

In order to emphasise the importance of history- ting, I have recently in my outpatient department ted the provisional diagnosis after taking the history; e diagnosis after examination; and the final diagnosis er all investigations were carried out, the patient ing admitted to hospital if necessary. These diagnoses have recorded in 100 consecutive cases, but I have of urse only used cases presenting a diagnostic problem. Cases sent solely for treatment, where a full diagnosis had already been made, were not included, neither were those in which the doctor's letter supplied foreknowledge of a physical sign of major importance, such as significant hypertension.

Most doctors send patients to the outpatient department with only a brief outline of the main complaint, and all such cases were suitable for the inquiry. The results are as follows:

The diagnosis reached after history-taking alone was unchanged by examination or investigation in 68 cases out of 100. For example:

Diagnosis after history: bronchiectasis.
Examination: basal râles.
X ray (bronchogram): bronchiectasis.

In addition to these 68 cases, the diagnosis after history-taking was *substantially* correct in another 6. For example:

Provisional diagnosis: rheumatic heart disease with early failure.
After examination: mitral stenosis with early failure.

In a further 8 cases, the provisional diagnosis was correct, but examination and investigation contributed important findings to the final diagnosis, unsuspected during the history-taking. For example:

Provisional diagnosis: osteo-arthritis of spine.
After examination: the same plus glycosuria.
After investigation: osteo-arthritis of the spine plus diabetes.

In 1 case the provisional diagnosis was correct, but examination was misleading, and a change of diagnosis was made which turned out to be wrong, the sequence being duodenal ulcer; gallstones; and (after two X rays) duodenal ulcer.

In 12 cases no provisional diagnosis could be arrived at after taking the history—only a number of vague possibilities presented themselves. Examination provided the clue in 5, investigation in another 5, and the remaining 2 were still vague at the end of the diagnostic process.

In 5 the provisional diagnosis was frankly wrong and had to be amended—in 2 cases by the examination and in 3 after further investigation. For example:

Provisional diagnosis: cervical root pain.
After examination: the same.
After X ray: pulmonary tuberculosis. (Re-examination failed to show physical signs but the possibility should have been considered before it was revealed by X ray.)

COMMENT

Before attempting to assess the significance of these results, we must bear several things in mind.

The first is that history-taking comes first in the diagnostic sequence. There is no intention of belittling the importance of examination. If examination came *before* history-taking, the results might be equally striking, but no sane physician works in that order.

Secondly, what we call history-taking really takes into account much more than the statements of the patient. We do not take histories with our eyes shut. We know how old the patient is, how he walks into the room, whether he is pale or flushed, thin or fat, healthy looking or cachectic, and in some cases we may know a great deal more, that he has a facial paralysis for instance or a tremor of the hands. All this is observed before the provisional diagnosis is made.

Thirdly, it must be emphasised that the diagnosis made after history-taking is in any case only provisional, and requires confirmation before any competent physician would act upon it. One would not give insulin on a history of thirst and polyuria, nor liver extract upon breathlessness, pallor, and paræsthesia. Again let it be emphasised that no case is being made out for neglect of diagnostic care and precision. On the contrary, the claim is put forward that because history-taking will lead to the right diagnosis in so many cases, it is an art to be acquired, taught, and constantly exercised, and *my trying to explain how to do so, for that will vary for* each one of you, but by my pointing out their existence and their nature, so that you may deploy your own natural resources to the best possible advantage.

Some of them are peculiarly British. For example there is our disinclination to adopt any course of action from which either divergence or retreat is impossible; and when we do accept a course of action, we often seem to choose the hardest way of completing it, as if unnecessary labour were something to be sought. Linked with this is our inclination towards stability: sometimes for a dangerous let-be stability, and this inclination you must temper; sometimes for a stability which will provide a stepping-stone for the next forward social movement, and this you must cherish tenderly. The national answer to such dilemmas, and often a successful one it is, lies in compromise, acceptance of the best existing hypothesis or plan, preparedness to await a better; an answer which is the very basis of all communal life, whatever the size of the unit. Indeed the only circumstance in which your own attitudes must be utterly uncompromising is when you encounter bad faith.

We may note, also, and as an opposing trend, our insatiable desire for new knowledge; this you must adjust carefully and with understanding, for your patients may fail to discriminate between the good and the bad in the mixtures of science and pseudo-science which they may hear or read. Even when they make the correct choice, you may have to help to ensure that their characteristic impatience for action to be taken in the light of the new knowledge does not necessarily mean the hurried uncritical discarding of existing arrangements.

CULTS AND VALUES

Although you will have discovered for yourselves that all men are not cast in the same mould, and although you may have met here some individuals cast in curious moulds, when you go out into the world your experience of different types will be greatly increased, and you will encounter the tendency of types to congregate in groups, some of which may actively or passively obstruct your educational work. Some such cults may be stimulating, because they are providing an outlet for the attitude of mind of those who are unorthodox, but who do not wish to impose their views upon the majority; whereas the difficulties you may have with an obstructive group are determined by the belief of each adherent, however sincere it may be, that one view alone is permissible: a belief that will often be understandable to you as the only one possible for the persons who hold it, if you realise that it has been reached without the use of any cerebral process with which your physiological studies have made you acquainted. *Many of these* people see and hear by proxy—they depend for the information on which they base their views upon someone else, or upon someone who knows someone else; and the best piece of advice I can give you is that in your attempts to overcome their prejudices you should not begin by provoking uncompromising opposition. There is one cult on which you must make continuous, total and unmerciful war—the cult of the obsolete: it can do nothing but harm, and *its adherents must* be destroyed utterly; they are too apathetic and too ignorant to debate any proposal for change.

Then you must realise that you may share with the laity our queer national topsy-turvy notions of relative values: even in large issues, if a cause be a lost cause you may find your fellow-citizens cling desperately to it in spite of all your incontrovertible arguments.

You must remember, too, that public opinion does not necessarily reflect that of the most intelligent citizens, and still more that changes which you may desire in public opinion are not to be brought about by the influence of the relatively few of exceptional ability, *but usually by those* possessing powers of persua who may be less gifted. Excluding the demag the man of average intelligence has most influence o average man, and at him your educational camp should be directed; any effort which ignores this pri is sure to be only partly successful. And when d with the average man you must be on the watch assess what Nicolson writes of as the "immense p played in human affairs by such unavoidable and unrecognisable causes as lassitude, affability, pe affection or dislike, misunderstanding, deafness, inc plete command of a foreign language, vanity, engagements, interruptions, and momentary stat health." On such flimsies may hang the fate of causes, or even that of nations.

A UNIFYING PURPOSE

It is time to draw together such threads as I been able to provide for my argument. I hope you will have realised that I have proposed to y merge your professional problems with those of society in which you find yourself, and to inclu *your scientific mission* personal, social, and eco problems as well as vocational problems. To l yourselves to these last would be to fail to assume proper responsibilities in society. The ultimate pr was defined by William James as the search fo moral substitute for war—some unifying purpose, w would stimulate a spirit of altruism and self-s on a large scale, in the absence of human con I believe that you and the other young men and wo who are now entering our profession from th schools all over these islands, should grasp the op tunity of so sharing in the education of our that it will find this moral substitute for itself in *effort to secure the best possible* mental and phy health for our people. To that end, the qualities w you must cultivate are those set down by Francis Ba four hundred years ago:

> Desire to seek; patience to doubt; fondness to medi slowness to assert; readiness to reconsider; carefulnes dispose and set in order; neither affection for what is nor admiration for what is old; and hatred of every k of imposture.

What is to be your tactical objective? To edu society in the place of science, and in particular of med science, in its life, so as to secure conditions in whi can help to provide for the intellectual satisfaction and the spiritual and physical welfare of that society receding objective, for at any given time so knowledge is neither complete nor final, wherein li charm of its pursuit.

By planned campaign or by isolated—even brillia *skirmishes? Surely by planned campaign,* which be flexible enough to enable you to make use of opportunity of time or place.

By steady advance or by impulsive crusade? Su by steady advance: have we not just learned th individual, no community, no nation, can co to sustain a maximum effort? And a long be the campaign is bound to be.

How shall we, or our children, recognise any succ *A difficult matter, on which I cannot offer you* guid for the beginnings of success may be recognisable on retrospect.

Finally I crave your leave to revert, for the last ti to my habit of asking you to take away but one p from any address of mine. And so I shall end by sug ing to you that your life's work will be in M. L. Ja words to prove yourselves "worthy to share the com and labours of those whose business it is to seek truth and to make wise use of what they find, b seekers and happy finders." Towards the accomp ment of that end, the best of good fortune go t each one of you.

Symptomatic treatment.—In the absence of treat- which is known to modify the course of the disease, ile waiting for a diagnosis to be made or for cure to place, what can be done to relieve the symptoms? we have analgesics from aspirin to morphine, otics, aperients occasionally, a linctus or inhalation, nany simple nursing and dietary measures.

What psychological treatment is necessary?—This es both to organic and to psychogenic disease. It e divided into: (*a*) psychotherapy, which may be ing from simple explanation and reassurance to ment in a mental hospital, and (*b*) therapy by bos. The latter has to be distinguished from tomatic treatment.

e frequency with which placebos are used varies sely with the combined intelligence of the doctor is patient. The more intelligent the doctor, the more e make use of explanation, reassurance, and, when ssary, an honest statement as to why medicine will o good. The more intelligent the patient, the more he heed the doctor's statement and advice. In this exion, intelligence and social status do not always ogether. The point is that the prescription of a ebo should be a deliberate act and not a conditioned x, and it should be an invariable rule that it must mething which can *do no good*. The greatest obstacle he intelligent practice of medicine is the habit of g something which *might* do good. Then if the ent improves, the reason remains obscure (but see er 5 below).

must be clearly understood that a placebo is given he mental comfort of the patient, not of the doctor, that whereas it may occasionally be expedient to ive the patient it should never be done at the risk eceiving oneself. Placebos should therefore consist he simplest possible ingredients such as infusion of ian.

he above principles are primarily designed for the in which a diagnosis has been made. In other cases an of therapy is just as necessary. The first question n is: how can an accurate diagnosis be established? l the second: am I justified in withholding therapy il it has been made? The answer is often unequivocal. suspected pernicious anæmia or carcinoma of the nach, it is always mischievous, sometimes criminal, reat before investigating. In other cases the decision ot so easy, for instance in a case of high fever. Here decision will depend upon the degree of likelihood t the provisional diagnosis is correct, the availability liagnostic aids, the danger of non-intervention, and the ger of wrong-intervention. In a remote country rict or on active service, I would give sulphaguanidine an acute febrile diarrhœa. In an urban practice I ld at least send a stool for bacteriological examination ore doing so, even if, in a severe case, I decided to rt treatment while awaiting the result. Finally in h. cases treatment may often be designed to give gnostic information, which comes under the important ding of:

. *The therapeutic test.*—This is usually wrongly carried . The tendency is for therapeutic timidity to accomy diagnostic doubt—"I gave a small dose of sulpha-azole in case it turned out to be pneumonia" is ocious therapy.

he right approach to the therapeutic test is this: am not certain. Therefore I will give remedy X in *l doses* for *x* days" (the usual period in which a ponse is likely to occur). "If it is disease X, then he l respond and I will know the diagnosis and continue atment. If there is no response I will try remedy Y in same way—or I will make further investigations into cause."

I make no apology for this elementary explanation cause I know how rarely a therapeutic test is properly plied. The point is that, used intelligently, every atment becomes a therapeutic test, thus aiding stage stage in the diagnosis. For instance, it may be spected that a headache is psychogenic. If the placebo contains aspirin, no useful information is obtained; the diagnosis is merely obscured. If it is dispensed on correct placebo principles (paragraph 4(*b*)) and the headache is regularly relieved, the diagnosis of psychoneurosis can be made with some confidence.

Finally, there is:

6. *Experimental therapy designed for the purposes of research.*

It is beyond the scope of this essay, but if such trials were properly planned with the necessary controls an enormous amount of valuable information could come from careful experiments in general practice, particularly as to the value of many accepted or advertised remedies in minor ailments.

I can think of no disorder in general practice that cannot be dealt with according to the scheme which has been described. Set out at length, it may appear extravagant of time; but actually it is merely a mental habit once the principles are grasped, and it is quite unnecessary to *think* in terms of 1, 2, 3, and 4. Nevertheless, lack of time is usually made the excuse for bad work. It is quicker to prescribe a bottle of medicine than to examine the patient properly and explain the nature of the illness. This is equivalent to an admission of failure, and let it be noted that the patient for whom the bottle of medicine has been prescribed will probably return for another and another, and what is more serious, an anxiety state may be induced, whereas explanation and reassurance might have finished the treatment in one consultation, thus saving time in the long run. Perhaps we must admit that many of us still have one more category which is:

7. *Treatment hastily prescribed without regard to principle or consequence.*

None of us is perfect. Let us realise that no. 7 exists, but is something to be ashamed of. I suspect that in not a few practices it is the category which most nearly corresponds with normal therapeutic procedure.

No-one's considered opinions are entirely original; they evolve gradually and are much influenced by discussion. Prof. J. C. Spence first used the words "teaching the art of consultation" to me, though I have practised the method for years. Dr. G. W. Rippon, of Sheffield, himself a general practitioner, first gave me the phrase "therapy designed not to deceive oneself."

SOCIAL MEDICAL TEACHING

W. Melville Arnott
B.Sc., M.D. Edin., F.R.C.P.E., M.R.C.P.
PROFESSOR OF MEDICINE

Thomas McKeown
M.D. Birm., D.Phil. Oxfd, Ph.D. McGill
PROFESSOR OF SOCIAL MEDICINE

F. A. R. Stammers
C.B.E., B.Sc., Ch.M. Birm., F.R.C.S.
PROFESSOR OF SURGERY

From the University of Birmingham

Both the Goodenough Committee and the General Medical Council have emphasised that the scope and method of undergraduate teaching in social medicine "are matters in which there is much room for experiment." In addition to a fuller discussion of the preventive services, they anticipated that instruction should be extended to include the more ambitious aim of influencing the clinical teaching so that due emphasis is given to the relation of the social environment to individual cases. In our view this aim can be realised only if accepted as the responsibility of all clinical departments. We here describe briefly the experience of a first year of joint social and medical teaching in the departments of medicine, social medicine, and surgery at the University of Birmingham.

We state first on what grounds we value this teaching. Since it has been supported by considerations in which never on any account to be neglected whatever may be the facilities available for investigation.

Finally, let it be remembered that these cases were all diagnostic problems sent for solution, and seen by me for the first time, and that the histories were taken not in the leisured atmosphere of the consulting-room but in a busy outpatient department in the presence of numerous students. With some help in routine examinations (blood-pressures, reflexes, &c.) the average time spent on each patient is unfortunately less than twenty minutes and this includes teaching and the dictation of brief notes.

On Therapeutics

How many doctors today think that they have the modern outlook in therapeutics because they treat sore throats with penicillin lozenges and prescribe stilbœstrol for menopausal flushing? And how many show their complete misunderstanding of all that modern therapy implies by prescribing vitamin B$_1$ for sciatica, by giving digitalis in inadequate doses to the wrong patients, and by retaining a belief in expectorant mixtures, not pausing to consider whether their results are due to the treatment prescribed, to its psychological effect, or to spontaneous recovery?

The new therapy, instead of being hailed as a welcome revolution in medicine, has simply been looked upon as an addition to knowledge, in no way modifying the use of the older remedies. In this year of 1947, I read in the examination paper of a final-year student the words "diuretics such as pot. cit. or mersalyl," as if these were equivalent. It is like saying: "The journey can be made by stage-coach or by aeroplane." And from two current textbooks I cull the following information:

> (In angina pectoris) "the daily bath should be advised to keep the skin active" (no comment).
>
> (In acute nephritis) "diuretics should not be used *at least until diuresis is established*" (italics mine).

In other words, if you use a drug be sure to use it at such a time and in such a way that you will be quite ignorant of its value and almost certain to deceive yourself as to its efficacy. So long as that is the teaching in therapeutics from the writers of textbooks, we cannot expect rational therapy from the majority of the profession.

We, the teachers of medicine, are often criticised, and often deservedly, for not applying ourselves sufficiently to the problems which the student will later meet in general practice. It is a fact that some teachers are too prone to discuss Cushing's syndrome when they should be teaching the causes and treatment of headache, but if the critics infer that we ought to be teaching how to write a prescription for a diaphoretic in bad Latin, I for one refuse to waste my time on such anachronisms. Yet we cannot hope to get rid of the bottle-of-medicine tradition without facing the problem and giving the prospective practitioner something to put in its place. It is not sufficient for us to teach the use of parenteral penicillin and blood-transfusion, leaving the student quite ignorant of how we, his teachers and exemplars, would tackle the problem of treatment in general practice ourselves.

CHANGES IN OUTLOOK

The therapeutic revolution to which I have referred has necessitated certain fundamental changes in outlook.

Firstly, diagnosis is far more important nowadays than ever before. For instance, before penicillin, a missed diagnosis of bacterial endocarditis was unimportant; today it may amount to malpraxis. In the old days the immediate diagnosis of pneumonia or meningitis was not essential; today it may be life-saving. With more potent and specific remedies the need for accurate diagnosis and control should require no emphasis.

Secondly, these remedies must be properly used. With *mist. expect.* it matters little whether $^1/_2$ oz. or 1 oz. is given, and whether every four hours or three times a day. With sulphonamides, with insulin, with iron, digitalis, with thiouracil, the dosage, frequency, and of administration are all-important.

Thirdly, in the old days when we had no real remedy for anything, we had to treat everything. Today when we can efficiently treat so many illnesses we can usually afford to admit honestly when we are beaten. There is less excuse than ever for the diaphoretic mixture, febrifuge, and the aperient.

Fourthly, there is a healthy tendency nowadays to admit the importance of psychological factors in the of disease instead of ascribing the cure to something We should therefore try to realise when we are employing psychotherapy so that we may use it rationally.

We who have the privilege—the very great privil of working in a well-equipped hospital with e diagnostic and therapeutic aid, with a team of y men to help in treatment and investigation, and all with the advantage of being able to discuss our lems with junior and senior colleagues, have a to those who are in the more isolated practice of medicine to pass on to them if not our facilities, at least the of our thought, and to apply ourselves to their problems as well as our own, so as not to disapprove without least attempting to show the way.

POSSIBLE REFORMS

What reforms then might be made in the teaching and practice of therapeutics?

First, I would divide the pharmacology textbooks and the *British Pharmacopœia* into two parts: the first dealing with remedies in current use, the second with remedies which are no longer used in modern practice. In the second category, I would put drugs like strychnine, calomel, hexamine, and strophanthus whose action it may be as well that pharmacologists should not forget, though I would not have them teach it to medical students. This would give the necessary authority for the omission of obsolete information from the curriculum, thereby defeating even the retarding effects of external examiners.

Secondly, I would inculcate the principle that therapy should always be approached as a scientific experiment. Often enough the result of the experiment will be known in advance, but at least it should be planned so that the answer will be as clear as possible at the end. With this aim in view, it stands to reason that major remedies should ordinarily be given one at a time unless their various actions are clearly distinguishable. In planning a therapeutic experiment, the following considerations seem to me to be universally applicable:

1. (*a*) *Is there a specific remedy for this complaint?*—Under the heading of specific remedies would come hormone therapy in clearly defined syndromes (insulin in diabetes, thyroid in myxœdema); vitamins in deficiency states such as rickets, pellagra, scurvy; penicillin and sulphonamides in the appropriate infections; antisyphilitic treatment; quinine and mepacrine; iron and liver used specifically each for its corresponding anæmia. Some operations come into this group.

(*b*) *Is there a specific remedy known to do good in the majority of cases, though not necessarily curative?*—For instance, gold in rheumatoid arthritis, or barbiturates in epilepsy, &c.

2. (*a*) *Although there may not be a specific treatment, is there some major corrective to the disordered physiology of the disease?*—Here we have digitalis (properly used) in heart failure; mercurial diuretics in œdema; saline in dehydration; adrenaline in asthma; blood-transfusion in anæmia and hæmorrhage; plaster and physiotherapy in arthritis; and some minor or major operations.

(*b*) *In this connexion, is there a way of life which I should advise the patient to adopt or to avoid?*—For instance rest in bed, exercise, diet, weight reduction, change of environment, or occupation.

SATISFYING THE EXAMINER

To prevent waste of time and labour has again become a national duty. An obvious form of economy, which has parently escaped official attention, is to arrange for all candidates to pass their examinations at the first attempt. ding legislative action to this end we offer a short series of articles whose perusal should ensure success.

AS THE EXAMINER SEES IT

HE student facing his qualifying examination can dly feel with Robert Louis Stevenson that to travel efully is better than to arrive. Nevertheless it is true, Sir Walter Raleigh (the one-time professor of English rature at Oxford) was wont to remind his own students, t there are *two* crucial examinations—Final, and the eat Assize. Translated into advice suitable for the dical faculty, it means that the student should seek t to become a good doctor, and all things shall be ded unto him. He is more likely to get through Final e takes it in his stride rather than if he crams for it.

THE YEARS BETWEEN

The first thing, then, which the student has to learn that it is useless to leave reading for Final until the al year. Medicine, being a practical art (or, if you like, applied science), cannot be learned from books. The mer who does not spend his days in the fields or the ippons or the stackyard can never be a good farmer, r pass any searching test of good farming. The read-g of books may help him to interpret or to enlarge his perience, but without the daily routine of farm work will never know much about farming however many tions he may have gathered about it from reading oks.

So too in medicine—we learn primarily by doing. the doing of it, what we have experienced and what e have read become part of us, instead of something traneous which we so easily *mislay* when we most ed it. The Final hurdle is surmounted mainly because the training in the wards, outpatients, and clinic om, whereby the student exercises his intellectual uscles—especially in the days of his apprenticeship clerk or dresser. Unless he builds solidly there, the undations of anatomy, physiology, and pathology pporting each acquisition of experience in the wards, e will labour in vain. No-one else can do the building r him. It takes time to learn and to understand, id the clinical years are short enough even for the mple fundamentals which the sympathetic examiner ks of the Final candidate. All too often those years e largely wasted because the student relies primarily reading books or on listening passively to a popular acher, rather than on his own painful struggle to ad his way. The child who first tries to draw a house ill only be discouraged and bewildered by the perfect icture drawn for him by an architect; but let him have aper and pencil and *try for himself, and after* some weeks e will be drawing something with a roof and windows and door which, though crude and simplified, has a vitality it which could never be got by merely tracing some dult's drawing.

“And so what?” the examination victim may ask. et us look back to the first days of young Galen's clerk-ig, and to his first patient. He has probably forgotten y now, but it was a Mrs. Jones who had jaundice. ould he but remember all the beautifully concocted linical *aperçus* of the case which clinical tutor and hief poured into his receptive noddle, Final would ave no terrors. Alas! however, it leaked out of his nderstanding as through a sieve. *He did not know at* he time that it was far more profitable to listen to rs. Jones telling him about herself, than to the medical ator. He ought to have read about jaundice in his xtbook of medicine and worked out for himself what e was to look for when he examined Mrs. J. He ought o have looked again at the detailed anatomy of the bile and pancreatic ducts, and reminded himself of various points in the physiology of bile secretion, in particular the essential differences between obstructive and other types of jaundice. Fortified with this, he could have examined Mrs. J.'s stools and urine with intelligent anticipation; and after all this discipline he would have found that the Chief's bedside talk illuminated and drove home essential points which he had already discovered for himself. Moreover, if he had taken a sheet of paper, headed it with Mrs. Jones's name and the final diagnosis, and summarised the salient features of her case and his own discoveries, he could have filed it away for later reference, together with his notes on Mrs. Brown and her thyrotoxicosis, Mr. White and his disseminated sclerosis, and the rest. By the time he had finished his clerking and dressing, he would have had a collection of examples which would almost have made up an elementary textbook of medicine, written in terms of personal encounters and living experience. In his Final year, he could have revised large tracts of his subject from his own notebooks; jaundice, for example, would remind him of Mrs. Jones's impacted gall-stone, Mr. Black's carcinoma of the head of the pancreas, young Tom Noddy's acholuric jaundice, and so on.

The student, no doubt, feels that he has not the time for all this; the art of medicine is long and time is fleeting, and nowadays so many teachers claim his attention that he is left with no private leisure for thought or contemplation. Let him be confident, in any event, that the examiner will be as delighted to see evidence of clinical observation and *nous*, of time spent at the bedside and in the clinic room, as he will be unimpressed by a catalogue of facts which are repeated parrot-wise.

THE DAYS BEFORE

And so at last the student comes to Final—an examination which is a test not only of knowledge but also of physical stamina. It is silly to work up to the last moment, trying to stuff the brain with last-minute facts, battening down the hatches so that for a few days at least they will not escape. A stuffy brain is an unreliable tool with which to tackle Final. The student would do far better to spend the last week before the examination on the golf-course, or loafing on the top of a hill, gazing aimlessly at long views while he airs his red blood-corpuscles. This he can do without panic, the more good-humouredly he accepts the fact that even if he is inadequately prepared for the test, what he can cram in a week will make no difference. Let him go to bed early, and if (as is natural) he cannot ignore the shadow of coming events, let him nevertheless cultivate a protective fatalism. If he must read, there are always thrillers to occupy the time; if he must hover round the flame of medicine, Osler's *Aequanimitas* is as good a book as any to keep him out of mischief.

APPEASING THE EXAMINER

At last the day comes. He has sat “padded up” long enough, and now he must go out to bat, strung up with that curious feeling in the pit of the stomach—*but, if he has taken my advice*, with an untired eye which is likely to see the ball well from the start. There are the questions and he has three hours for them. *He must not allow himself to be hurried.* Twenty minutes or so looking at the questions, drafting out the main lines of his answers on scrap paper, will save time in the end. This leaves him with half an hour for the actual writing.

the sentiment has at times been more conspicuous than the sense, many clinicians no doubt still feel they have heard no convincing reasons why the attention of the student should be directed beyond diagnosis and treatment to the social environment. The arguments for this are none the less compelling, and deserve simple statement:

1. Economy of medical effort requires that nothing should be treated once that can be prevented, and nothing should be treated twice that can be cured. The student should learn that it is as wasteful to treat anæmia secondary to ignorance of diet without educating the patient as to treat anæmia secondary to organic disease without attending to its cause.

2. Examination of such indices of morbidity as are available shows that health has improved in the past largely because of changes in the social environment. Continued improvement can be anticipated from this quarter if social medical research can define more exactly the relation of specific environmental factors (as distinct from the complex of variables described loosely by such terms as "poverty") to health and disease. Efforts of sociologists, statisticians, and others cannot bring this research to fruition without coöperation of medically qualified workers whose training has made them alert to the significance of social variables.*

3. Recent *legislation* provides for vast changes in the organisation of medical and social services, and the success of such plans depends on both medical and lay officers. For example, the Government has provided for the employment of the handicapped worker in the Disabled Persons Act (1944). It is essential to the operation of this Act that the doctor should realise that his responsibility includes return to employment as well as treatment of the disabled patient.

4. Inevitably the doctor's work imposes other exacting social responsibilities. With his knowledge of prognosis he is often the only person who sees clearly at an early date the steps that can be taken to minimise the effect of illness on the life of a family. His attitude to such problems is partly determined by his training in the teaching hospital, where special care is needed to ensure that improvement in techniques of diagnosis and treatment is not bought at the price of an impersonal service.

METHOD OF TEACHING

If these reasons are acceptable, it is necessary to consider how such instruction may best be incorporated in clinical teaching. Formal lectures have limited value, for students acquire their clinical habits not from academic lectures but from the practice of the clinicians by whom they are trained. In our school we have therefore proceeded on the assumption that the integration of social with clinical teaching is essential. It was initiated in the introductory clinical course, of which five mornings were devoted to social medicine. On each morning students attended in groups of twelve at demonstrations, one of which, given jointly by the professors of medicine, social medicine, and surgery, was arranged as follows:

Selection of Cases.—Cases for demonstration were selected from the medical or surgical wards by the professor of medicine or the professor of surgery. Presentation and discussion of a case require roughly half an hour, and it was convenient to choose three for each morning, usually one surgical and two medical cases.

They were chosen to illustrate various social medical problems, care being taken to focus attention on common rather than unusual situations.

Preparation of Case-histories.—The case-history was prepared by the house-physician or the house-surgeon, assisted by the almoner. It consisted of a complete clinical history, and a social history specified under the headings of personal background, work, family, home, food, budget, summary and comments.

Presentation and Discussion.—Cases were presented by a member of the clinical staff, usually the professor of medicine or the professor of surgery. The phy features were reviewed in the presence of the pa the social features after he had withdrawn. Th interrupted by the withdrawal of the patient, in w presence discussion of social circumstances was avo the complete social and medical history was co by one person. The case was then discussed by professor of social medicine, who drew attentio the social medical problems which it illustrated. T almoner contributed to the discussion which followed.

The close integration of clinical and social factors illustrated in the following case.

A woman, aged 33, was admitted to hospital comp of weakness and dyspnœa. She was found to have a r count of 3,070,000 per c.mm. and a hæmoglobin of 6 100 c.cm. Conventional treatment with iron and a g diet restored her to normal, but an inquiry into the stances in which she became ill revealed these facts:

1. In addition to caring for a husband and two ch aged 7 and 3, she was employed in a factory packing c for 30 hours per week. This yielded her a weekly wag of which £1 was spent on the care of the younger child her absence at work.

2. Home relations were not harmonious, partly becau husband had recently returned after several years of and the patient's fatigue and malaise had resulted in temper and friction. She went out to work agains *husband's wishes, apparently for the* companionship of factory.

3. She had a very inadequate conception of food va and her administration of an adequate budget was p She herself had been taking roughly 1200 calories per d with insufficient iron and vitamin C.

Further treatment consisted of dietetic instruction, advice and explanation to the patient and her hus coupled with a recommendation to cease factory w A health visitor was commissioned to give assistance.

The success of these demonstrations encouraged to make them a permanent feature of *clinical* teach and they are now given once a week for students atta to the medical and surgical units. For the first weeks of the student's clerkship cases are prepa and demonstrated as described above. In later we students prepare and present their own cases.

Social, as well as clinical, aspects of the case-hi are prepared by medical staff or by students, and whole case is presented by one person. Social or clin problems may be unduly prominent but are not sepa and should be considered together.

Only those facts which appear to have a direct bea on a case are included in the social history. Len accounts of personal difficulties are avoided, and attent is focused sharply on matters arising from the 1–4 enumerated above.

Since demonstrations have limited value unless ported by ward teaching and practice, students asked to consider social circumstances in all cases they are relevant. The practice of confining inquiry to a few selected cases prepared in great d presents the subject as a specialty which merits occasional consideration.

Since we think it important that examinations reflect this teaching, the final medicine paper year at Birmingham included a question on the rel of the social environment to illness.

"... The first step would be to entrust the teaching of basic medical sciences to a personnel actively inte in the teaching of medicine. The second step would a reform in the curriculum. . . . Let the preclinical surrender some of their hard-won time to the clinic in first and second years. . . . Let the clinic surrender time in the latter years to the basic science faculties. . . . the inclination of the average student to treat with pa in his first years and to understand the underlying natu the disease process in latter years be thus gratified." Dr. DE WITT STETTEN, jun., in an address to the New Y Academy of Medicine.

IN THE EXAMINATION ROOM

hen confronted with the patient consider the clinical roach with regard to the time allotted. In general, her strictly limited or comparatively liberal, this is nefully wasted. Don't dwell unduly on the history. eat deal of experience is required to extract a useful nnesis, a fact of which every examiner is aware, and vance is made for difficulties in individual cases when deafness, stupidity, or reticence of the patient are embered. Above all, deal first with essentials. If omplaint is related to the legs let us say, inspect the first of all. More than once I have seen a candidate bsessed with the importance of a complete examina-, that he started at the crown of the head and failed each the lower extremities before his time was usted. Thoroughness is all right in principle, but automaticity lacks a sense of proportion and alienates pathy.

isten to directions and respond accordingly. You may sked for a diagnosis or alternatively for a report. In one case, a plain answer is required; in the other, iscursive conversation is permissible. Anomalous ures may inspire a hesitancy in conclusion, but many lidates forget that textbook descriptions are compo- of signs and symptoms, some of which are present ndividual instances but all of which will be found in e. Diagnosis is the balance of probabilities, and the miner is impressed by the method of approach at least uch as by skill in deduction.

ere is of course an irreducible minimum which cannot efined, since all examiners have their shibboleths, pet aversions, their prejudices. But as a rule there difficulty in recognising the occasions when swift nary judgment and sentence are legitimate. The emically brilliant young lady who, confronted with ge aortic aneurysm, recommended “ biopsy of the our ” is a case in point.

mplicity and fundamentals. In a pass examination expected that the candidate can recognise the first the second heart sounds, and his inability will not ondoned by his facile enumeration of the third, fourth, (for all I know) the fifth sound. And remember a clinical examination presumes clinical methods. shocking to meet the refusal to give an opinion upon stolic murmur before being provided with an X-ray ograph of the heart, an electrocardiogram, and an nation of the erythrocyte-sedimentation rate. Doubt- this attitude is the result of bad teaching—an appy result, for the sins of the father will certainly isited on the child. If directed to examine a certain when only a few minutes are allotted, get to work waste no time asking the patient questions. The miner is not entirely devoid of reasonableness, he planned his request with due regard to the circum- ces. And whatever he asks, take him literally. On asion he may seem mad, but there is always method is madness.

have been tempted to present for clinical examination umber of perfectly healthy subjects—a temptation which I have never yet succumbed, for such a test ld be almost unreasonably exacting. Keyed up to ectation, a candidate naturally looks for abnor- lities. A gaoler is prejudiced against a prisoner in the k; his presence there signifies that he must have done nething wrong. And the atmosphere of hospital and ical examination is conducive to the discovery of ease and abnormality. For this reason the adjective ight” is always in evidence. Be a man, avoid it. It is oor bluff, which gains nothing; whereas a courageous neanour of dogmatism in a positive discovery or of qualified assertion in the negative commends itself the examiner, who will conclude that the candidate s the right temperament and will make an efficient actitioner even if he still has much to learn.

DEMEANOUR UNDER FIRE

Perhaps it is asking too much to suggest that the viva-voce interview should be regarded with pleasure rather than as a dreaded ordeal. Yet it really is intended to operate entirely in the examinee's interests. A man whose factual knowledge has otherwise been thoroughly tested can hardly bring about his complete discomfiture by even the most devastating performance across the table. Alternatively, academic deficiencies if not too extreme can be compensated by a good impression when such qualities as common sense and general capacity are being assessed.

Unfortunately many men are at their worst on such occasions. I say advisedly men, for women are on the whole far less nervous under fire. It may be that their coolness and self-possession are founded on the ability to exploit their “ weakness ” in relying on the chivalry traditionally accorded to their sex, and more than chivalry when their charms so demand. But I think they have a special form of courage.

It might be argued that this test of character operates adversely, on the principle that failure to exhibit presence of mind when personal interests are paramount denotes the likelihood of a similar failure on all occasions of emergency. There is something to be said for this somewhat harsh judgment, but there is good contradictory argument.

It is, I know, rather silly to exhort anybody not to be nervous, especially as in extreme instances the condition may lead to complete mental paralysis or to a curious compulsion to say the wrong thing when the right is known, to be conscious of the perversion and yet be helpless. But for average cases it is perhaps not silly to advise on the James-Lange principle the adoption of a confident exterior—to square the shoulders, to sit up, and above all to speak up. The majority of examiners are senescent if not senile. Their olfactory sense may still be strongly developed, but their auditory sense is rarely unimpaired, and the strain of listening, perhaps for hours, to a halting whisper or mumble will create irritability in the most placid. A correct answer may suffer through inaudibility, while an incorrect one gains no dividend.

In your encounter, believe that excessive faith in kindliness is better than the least suspicion of treachery. Don't look for the hook sticking out through the bait. Take the absurdly simple question at its face value, it is intended to put you at your ease; and give a straight answer free from qualifying phrases which reduce its value without compensating advantages.

If the answer is unknown, say so at once and let the examiner pass on to something else. Nobody expects omniscience. If the question is obscure, don't hesitate to request its elucidation: you run the risk of offending an interlocutor who may consider his meaning too clear for any misunderstanding, but it is a very small risk.

Avoid slang and with this I include unnecessary abbreviations. Life may be short, but it is not so short that odd tenths of seconds must be parsimoniously conserved. I have the impression that apart from laziness, medical students believe that there is something smart and technically professional in preferring the horrid word “ bug ” to “ micro-organism,” for “ doing a P.R. ” instead of making a digital examination of the rectum, for describing the teeth as “ O.K.,” and so on and so on and so on. In all honesty I have on occasion been compelled to ask whether “ P.A.” meant paralysis agitans or pernicious anæmia.

Examinations, however planned, are open to criticism. No modification could make them completely satisfactory. But whatever their faults there is no substitute.

Looking back over a long experience I can recall many instances when the quality of mercy has been strained;

of each of five answers. Even when he starts writing in earnest, additional ideas on the answers still to come will well up into his consciousness, and he will jot them down in the appropriate place in his scrap notes.

In order to qualify, you have to "satisfy the examiner." An intelligent approach to a question will go far to make him like you. He dislikes lists which you have obviously learnt by heart, all the more so if, as often happens, you get them wrong and thus betray that you do not understand what you are talking about. It is always wise, both in learning medicine and in examinations, to try to correlate medicine, surgery, and the rest with anatomy, physiology, and pathology. For example, you might be able to number off a whole platoon of manifestations of coronary thrombosis—if only you could remember them all. It is far less trouble to visualise the infarct of, say, the left ventricle, which wrecks it as an efficient pump (low blood-pressure, oliguria), causes left ventricular failure with œdema of the lung and marked dyspnœa (and maybe congestive failure as well), determines an inflammatory reaction in and over the *necrotic area* (*pericarditis, leucocytosis, pyrexia*, a particular form of myocardial pain, an abnormal electrocardiogram)—and so on. In this way the answer to even a "factual" type of question can be made to reveal clinical intelligence. With the less obvious type of question—for example, "Discuss the significance of pallor"—remembered facts are liable to absent themselves at an examination, and the approach from first principles will save much heart-rending. Think, therefore, of the anatomy of the skin, and recall its blood-vessels with their nervous control, and the tissues that surround them. What physiological and pathological conditions, local or general, can so affect the blood-vessels that they are relatively empty of blood: what conditions inside or outside the blood-vessels can obliterate them or make it impossible to see the normal colour of the blood in them? Here again, the student must have pursued this discipline throughout his clinical studies; he cannot hope to adopt it suddenly for an examination, it must be an attitude of mind which has already become second nature to him.

Spare a kind thought for your examiner, and *write legibly*. He wants to let you through if he can conscientiously do so. He is a very human fellow, and if he has already read through sixty papers before he comes to yours, he will be jaded and bored, though he will sternly discipline himself not to let that matter. Nevertheless, if he has to spend all his energies in trying to decipher what you have scribbled, you are "asking for it." You exasperate him, and then he is apt to say to himself "I suppose that I must not fail this chap because I cannot read his handwriting, but I would very much like to." Remember that your examiner is a friend, though a reasonably exacting and just friend. You are a fool if you throw that friendliness away, such a fool that you do not deserve to be made a doctor until you have learned better. It is true that the examiner knows that in Final you are probably not quite *compos mentis*, and makes allowances accordingly; but though he is not likely to plough you because you have irritated him, he will certainly be disinclined to stretch a point actively in your favour.

Write legibly, therefore; and if you can write good, clear, readable English your examiner will be cheered to encounter at least one civilised student. You will bias him into thinking that here is evidence of worthiness of entry into a learned profession, for you will have afforded him refreshment in what is usually a parched and arid land. This is a further argument against the use of lists—they are so wearisome, so unutterably boring to read.

Abbreviations, too, are irritating. In an examination paper they look like the product of a raw and uncultured mind. Not only do they bias the examiner towards thinking that you are a sloppy fellow, but also they may be unfamiliar to him. He will not like you if he has to waste time trying to puzzle out what they mean. To be able to spell correctly in your own tongue is also an advantage. I do not suppose that any Final candidate was ever ploughed solely on the grounds of bad spelling, but the man who writes sifelus, tubuclosis, falacea obviously cannot read, and ought to be referred back to the kindergarten.

Finally, do not hedge—your examiner knows what you are doing, and thinks the less of you for it; and do not try to bluff him, for he has had infinitely more practice at low cunning than you have.

CLINICAL AND VIVA-VOCE

I DO not flatter myself that I shall be believed if I declare that the earnest desire of the majority of examiners is to pass and not to plough. The idea of a contest is deeply ingrained in the mind of the average candidate, who visualises his opponent as a sadist, an arch-tormentor, a dirty fighter who disregards the Queensberry rules.

It would perhaps be hypocritical to represent a typical member of my tribe as an incarnation of all the virtues, with *charity* and *philanthropy* in the van; but I would emphatically maintain that so far from being an *advocatus diaboli*, he is the prisoner's friend or at least *amicus curiæ*. Let, then the more confiding accept me in this rôle. Those still suspicious may read on the principle that *fas est ab hoste doceri*.

PREPARATIONS

Approach an examination with at least a superficial regard for its professional relationship. The frock-coat, at one time our orthodox invariable uniform, has long been obsolete, and modern dress combines the consequences of compulsory austerity and sartorial indifference. Yet the function of dress is by no means negligible. The ass in a lion's skin, if he feels like a lion, is for practical purposes a lion. To look the part is to feel the part. Well, if the potential medical practitioner feels the part in crumpled flannel trousers and a pullover which would have made Joseph's coat look like deep mourning, there is no more to be said.

In the clinical examination the candidate is brought into close contact with patient and examiner. Deeply nicotine-stained fingers are not a recommendation. There is apparently an examination-halitosis, presumably the result of nervousness, which has to be accepted with resignation if regret. But an aroma compounded of carious teeth, stale tobacco, beer, and onions or garlic may to a considerable extent be avoided. I do not suggest that prejudice is deliberately injected as a result of these unpleasant associations, but it is by no means improbable that subconsciously they are not without influence.

Apart from a stethoscope, there is no necessity for a candidate to encumber himself with the apparatus required for a clinical examination. Only too often a bagful of gadgets is distributed on the beds and in different parts of the room, so that nothing is available when required and nervousness is succeeded by panic. Perhaps one's own ophthalmoscope is an admitted exception, but everything else will be provided. Avoid complicated machinery. I was once driven to distraction through an elaborate stethoscope with special attachments for auscultating at the apex, and at the base of the heart, and for respiratory sounds. So much time was wasted in screwing and unscrewing the particular section that no examination was effected. Some ladies bring a number of small handbags—possibly cosmetics are part of their armament—which are dropped or mislaid with maddening frequency.

for clarity, to all but the most expert of writers. igorous style uses strong terse words and phrases, full of meaning; it avoids vague and empty essions; its constructions are straightforward, roundabout. So it carries conviction. For good ce on style read Fowler's *Dictionary of Modern lish Usage*; A. P. Herbert's many articles in *Punch*; is accessible, Howie's recent address to medical ents on medical journalism[2]; and Clifford Allbutt's *s on the Composition of Scientific Papers*.[3]

is the duty of medical men, as educated and ential members of the community, to learn to speak and write well.

THE MEMBERSHIP

ME thirty years ago when I took the membership nination we were seventeen candidates assembled library of the College answering the written papers o successive afternoons, and entertained to tea ete with cream buns and a napkin handed to candidate on a tray by a liveried butler. Today, six hundred candidates write the papers. The s for the increase in numbers are obvious to body.

the past, medical education and training have been ht to be a most liberal education; but unfortunately lism has reduced the intellectual level of medicine. College, by its cultural and academic activities, vours to keep up the standard of medicine, and, eserving the structure of the membership examinas a test of general medicine and general knowledge, ntinues to fight the battle against narrowness tlook and extreme professionalism. Clearly the of the M.R.C.P. diploma is to show that a man is enough to be a consultant in medicine.

BACKGROUND

one who has groomed a large number of candidates he examination I am convinced that a great many nt themselves before they are ready. They need more mature in experience. Formerly a man had done three years of house appointments before ent up for the examination. He is the ideal candi-. The practice of medicine cannot really be set in books, and all good examiners know that the questions are those which cannot be answered of the pages of books. There is the story, doubtless ue, of an Indian candidate who left in anger three tes after the written examination started. On vay out he pounded the question paper with his fist ront of the invigilating censor and exclaimed in r—"This is *not* in Tidy."

ead up-to-date reviews of medicine and allied subjects. the latest copies of *Physiological Reviews*, *Medicine* timore), the *Quarterly Journal of Medicine* and other rterly journals in special subjects. Read *Abstracts Vorld Medicine*, annotations in *The Lancet*, and the ures delivered at the College right up to the date of examination.

ANSWERING QUESTIONS

ince very often the candidate enters the examination n in an acute anxiety state, he should make certain he understands the question asked. In extreme s he may write for half an hour on osteitis deformans n the question concerns arthritis deformans, or he even write an essay on impetigo when vertigo was nded. An error which is almost universal among mination candidates is to put into the answer all sorts things that are not asked. A famous professor eatedly addressed his class on this subject: "When I ask you for the description of a lion's tail I do not wish to see a description of the lion himself." You should read the questions very carefully, make a plan for each answer, answer *only* what is asked, try to be precise and concise, and whenever possible weigh the evidence for and against a particular view.

Too often a candidate merely glances at the question, sees the name of a particular disease, and then covers innumerable pages with everything he knows about that disease. And even where he fails to make this error, he is unlikely to use whatever critical faculty he may possess in the discussion of the subject in hand. Indeed, concise statements made on good evidence are seen much too infrequently in examination scripts. Nearly always answers could be greatly improved if only the candidate would first get out a plan of what he intends to say, putting emphasis on what is really important.

The man who strives to fabricate complete lists of diseases including rarities seen once in a lifetime rarely wins affection: every examiner longs for a concise answer which clearly states the general principles involved and the evidence for and against. Too many scripts show evidence in the writer of what has been called intellectual constipation and verbal diarrhœa. Bad spelling is of course rife in all examinations. I suppose most examiners school themselves to ignore it, though it must always be difficult to avoid being prejudiced against a candidate who repeatedly mis-spells a word which is actually printed in the question paper. Candidates unable to spell correctly should be careful to omit from their answers all reference to famous men in medicine whose names have been given to diseases. But be sure to attempt one or both language questions. The marks gained for good translations may be enough to turn the scale in your favour.

In confidential moments the censors tell us that throughout the membership examination ignorance of chemistry is abysmal. Answers to questions on such subjects as tetany, alkalosis, or extrarenal uræmia are, they say, so pathetic as to suggest that the Chemical Society in 1947 must indeed be celebrating not its centenary but its foundation! One man is said to have alleged that children get lead colic from chewing lead pencils, and another believed that asbestos is a vegetable substance! Surely it is time that doctors realised we are passing through a chemical age.

CHOICE OF LANGUAGE

Americanisms inevitably creep into examination scripts—"the findings identicate those above," "you get a better effect if you pyramid the dose," "she was premedicated with iodine," "he studies the icterogenicity of batches of serum, or polyagglutinability of the red cells, or hyperrugosity of the gastric mucosa." Already an occasional candidate is liable to be "motivated by considerations of particle size," and another dabbles in the "quantitation of urobilinogen in the urine." I have heard someone speak of insolubleising a chemical substance.

Candidates should avoid vulgar expressions—"he has rotten teeth," "he behaved like a drunk," "this is due to œsophageal piles," "that is the meat of the history." References to the patient in the viva as a bloke or chap are almost as indelicate as to call the urinary tract "his waterworks." In addition to what is merely vulgar there is also slang—"she is a controlled fibrillator under digitalis," "he is a hypertensive heart," "I thought I tipped his spleen," "she has been bismuth mealed." (Though not all examiners are innocent of using slang themselves. Outside the College I have heard the questions "Would you quinidine her?"—"Can an aneurysm cough up blood?"—"Prescribe me an expectorating mixture.")

I recall very few of possible injustice in this procedure to safeguard the public and at the same time oppose no unreasonable obstacle to prospective guardians of their safety.

AN M.D. THESIS

THE universities of Great Britain differ so widely in their requirements for the degree of doctor of medicine that in general the letters M.D. after a man's name have small and uncertain significance. In one case they may mean that a searching examination in medicine—written, clinical, and oral—has been passed at a high standard; in another that a modest thesis has been accepted and a gentle clinical examination has been negotiated; in yet another that the results of two or three years' able and intensive research in (say) pathology have been embodied in a thesis which has been accepted and awarded honours. Where theses are required, there is no doubt wide variation in the standard expected, and in some universities there are up to four categories in which, according to their quality, accepted theses are placed. It follows that any remarks here offered to intending writers of theses must be quite general.

THE SUBJECT

The first problem is the choice of subject. There is no harm in seeking advice about this, but to go to one's chief and say "What do you think I could write an M.D. thesis about?" shows a lack of enterprise that ought to disqualify at the outset. Rather put up a suggestion or two as a basis for discussion, and be ready with an outline of how a suggested subject might be tackled. A good adviser may approve, modify, or condemn; but the discussion ought to be stimulating. Many theses are written on clinical subjects. They usually record and discuss a series of cases of some disease or group of diseases, chosen for their rarity, or for their occurrence in special circumstances (as in one of the Services or some institution), or because they have been studied by special means (as by some new technique or in a clinic with a thorough follow-up). Most subjects of this kind are worth-while, provided the observation and record are skilled and thorough. The disease need not be rare. A comprehensive and detailed account of a few dozen cases of peptic ulcer, or of prostatic hypertrophy, or even of "bilious attacks," observed over a period of years by a general practitioner, would make a useful study. Writers who contemplate the clinical approach would do well to read Ryle's book, *The Natural History of Disease*.[1]

The therapeutic thesis, in these days of chemotherapeutic innovation, often describes the results of treating a series of cases with some new drug. If the choice of cases and of controls, the dosage, and the methods of assessing the results are well planned in advance, and if the writer makes his own observations, this is likely to yield useful if not startling information; but if the material consists of other people's routine notes of cases the writer has never seen, the result of its analysis, however skilfully statistical, is not likely to impress. An experimental subject will commonly be chosen by those working in laboratories, and by those who have the facilities for applying the experimental method to man; papers on such subjects fill the journals, and the good ones are good models. Other kinds of subjects, in plenty, are appropriate for M.D. theses; there are opportunities in most of the specialties, only purely surgical topics being excluded; medical history and medicine in literature should not be forgotten. The essential requirement is that the writer should observe and record something at first hand, and set his own little addition to knowledge in relation to what is already generally known. Only occasionally will a pure "review of the literature" of some subject make an acce thesis: it will have to be a very comprehensive and a highly critical one, not merely condensing writings of others into small space but assessing t value and building them into a coherent picture.

While the work is in progress the form of its ult presentation should gradually take shape in the wri mind. The sooner the better, lest he omit to observations that later prove necessary to complete evidence, or be tempted by short-sighted cu down too many bypaths leading away from his theme.

WRITING IT UP

When the work is complete it must be "written up" to some the most difficult part of the task. The u pattern of a thesis is Introduction; Statement of t and methods of observation; Results; Disc Summary; References; Appendices.

The *introduction* should be rather longer than of the conventional paper in a medical or s journal. The writer of such a paper assumes a reader a knowledge of the field in which he works refers him to a review, and therefore restricts his duction to what is immediately necessary to explain purpose of his investigation. The writer of a on the other hand is expected to show that he is f with important work already done on his subject, moreover, familiar with its original sources, not m with its dried extracts in the textbooks.

With or after the introduction there must be a *statement of what the author set out to do* and what methods he used in making his observations, what the value and limitations of those methods a Where methods have been devised or modified by author full description is called for; where acc methods are used accurate references to publ descriptions of them are usually enough.

There is no standard pattern for presentation *results*, but the writer should think carefully w method is most appropriate to his own observat Straightforward description and logical arrangement are essential. Tabulation is useful, so long as it is too complicated. Graphs or diagrams often co the information more clearly. The figures on wh these are based, the protocols of confirmatory e ments, and case-records (where these are not t substance of the work) can often be set out in appendix, leaving the main presentation more su and easy to follow.

The purpose of the *discussion* is twofold: to dr conclusions from the observations already set f and to show how these observations and conclus confirm, confute, or extend the observations and c clusions of others. Where the body of the work is l it may best be divided into chapters, each dealing w one aspect of the subject or one stage in the argu and each containing its own presentation of results a discussion.

At the end comes the *summary*, which should p the facts and the conclusions into a few short paragr emphasising what in the author's view are his c chief contributions. It need scarcely be added t the list of *references* should be accurate, should in only books or papers that the author himself has r and should be given in standard form with abbrevi according to the *World List of Scientific Peri* A long thesis is improved by a *table of contents* at t beginning.

No doubt all theses today are typewritten. M are bound. No-one quite knows whether the style finish of the binding should express the author's re for his university or his own estimate of the qu of his thesis; probably a modest binding is better.

Finally, an M.D. thesis should be written in En that is clear, smooth, simple, and vigorous. Cl goes without saying. Smoothness leads the wr thought into the reader's mind, because each sente is linked with its predecessor, and each has its own inte balance and appropriate emphasis. Simplicity is ea is the sort of thing which will happen to such a over his long case :

---

[1] London: Oxford University Press. 1936.

" Then the main points you have found here are weakness d shortness of breath for three months, pallor, purpura, iversal enlargement of lymph-nodes, and the spleen larged to the level of the umbilicus."—" Yes."

" That is correct. Now please discuss the diagnosis."— It might be pernicious anæmia."

" Oh ! Does a patient with pernicious anæmia have a leen like this ? "—" No."

" Or enlargement of the lymph-nodes ? "—" No."

" Or purpura ? "—" No."

" Well then, suppose we think of something else."—" It ght be thrombocytopenic purpura."

" Oh ! Does such a patient have enlarged lymph-nodes ? " " No."

" Or a spleen like this ? "—" No."

" Well now, what else have you to suggest ? "—" It ght be acholuric jaundice."

" Oh ! Has this patient ever been jaundiced ? "— No."

" And in acholuric jaundice are the lymph-nodes nlarged ? "—" No."

" And does purpura usually occur ? "—" No."

nd so the bell rings and the candidate has never n mentioned leukæmia ! Here he is up for an honours mination, having had forty minutes to take the ory, elicit the signs, and think about the diagnosis. s he suppose that blood diseases will be sorted out him by technicians who do blood-counts ? Clinical dicine has not begun to dawn on such a man. How a censor possibly consider him fit to advise another tor who calls him in consultation over a case ? He ld make the problem all the more confused.

THE VIVA

f you survive until the first viva remember that cimens and photographs are used mainly as pegs n which to hang questions. Thus a photograph of patient with obvious acromegaly evokes questions gigantism, basophilism, chromophobe adenoma, and rasellar cyst. You must know the clinical features, thology, and treatment of all such syndromes. Equally must be prepared to interpret radiographs, electrordiograms, blood-counts, and other laboratory reports. When shown a museum specimen in the viva you uld identify the organ and follow this up with a scription of the size, shape, and colour of the pathoical lesion. The diagnosis should always come last ; erwise if you come to the wrong conclusion, you will vitably lose everything. When it comes to describing e colour of the normal organs of the body most men are gularly bad. It is scarcely possible to persuade a ndidate in a viva to say that the suprarenal cortex is lden-yellow, the medulla slaty-grey, and the normal yroid red-brown. But scattered through examination ipts one sees such confusing descriptions as " the lour of a daffodil, an iris, a rose, a marigold, or a plum."

FUN FOR THE CENSOR

Does a censor ever get any fun at all out of the examinan ? I like to think so. One candidate, I am told, rote : " examination of the fundus reveals papal dema," and another " it is said that the face of a cretin like that of a constipated owl, but perhaps this is slight exaggeration." An examiner is occasionally ivileged to give an extra mark to a candidate with ceptional powers of human understanding, such as the an who said of the treatment of insomnia—" an tractive and agreeable marriage partner is advocated many." At one time a question was asked on thrax, but it is not recorded whether an extra mark as given for the statement that " in the case of an outeak of anthrax the animal must be burned or buried ive and the woolsorter must be boiled." Neither do e know what marks were allotted to the man who rote " in scarlet fever the patient should be strictly isolated and should have connexion with no-one except the nurse."

Sometimes, I understand, a number of examination scripts contain a remarkable answer which can only have come from a whole class of men having misunderstood a lecturer. The famous example is that in answer to a question on the treatment of hæmatemesis, where countless candidates said the patient must be given oyster soup. This was traced to a lecturer lately imported from Glasgow who had told them to give the patient " ice to suck." One cannot dismiss this subject without quoting the statement of a very earnest candidate who obtained good marks throughout a whole exam.— " in hypoglycæmia it is possible by the judicious use of adrenaline to restore the patient sufficiently towards consciousness that he can swallow himself."

In the final viva be prepared for questions on the history and classical literature of medicine. On the whole the censor of today despairs of meeting a really erudite candidate. One hot summer, during the July examination, one of them kept asking who was the author of *An Essay on the Shaking Palsy*. No answer was forthcoming, and in the end the President is said to have remarked kindly that in this modern age one could not expect to meet a candidate who had read anything beyond a textbook. In the words of a past president, himself a master of erudition, " it is a bleak prospect."

Reviews of Books

Textbook of Obstetrics

GILBERT I. STRACHAN, M.D., F.R.C.P., F.R.C.S., F.R.C.O.G., professor of obstetrics and gynæcology, University of Wales, obstetrician and gynæcologist, Cardiff Royal Infirmary. London : H. K. Lewis. 1947. Pp. 732. 45s.

ALTHOUGH the British Isles are provided with a goodly number of textbooks of obstetrics, and thereby with a great diversity of opinions, it is some few years since a new author made his appearance. We will state forthwith that Professor Strachan's book is a good book—comfortably orthodox, pleasantly written with a scattering of superlatives to give emphasis in safe places, bountifully illustrated with over 300 illustrations and 3 colour plates, and really well produced with clear type and (for these days) surprisingly good paper. Throughout it shows his conviction of the evils of what he terms too early interference and of the urge to interfere with even the normal course of labour.

There are nine sections, each of which is much subdivided, and the subdivisions are not numbered. The arrangement is unusual and leads occasionally to odd sequences. Of much greater importance, however, is the fact that no less than 275 pages—over a third of the total—are given to description of the normal. This is a great accomplishment. Probably the first two sections are the best in the book. The student receives detailed instruction in the preparation of the patient for, and the conduct of, a normal labour, and there is an excellent description of the objects and application of postnatal care. The third section, of only 36 pages, is concerned with the newborn child and its ailments. Although written by the pædiatrician to the department, it cannot be said to be notably better than similar sections in other obstetric textbooks. Condensation to this extent is always difficult.

In the treatment of gonorrhœa in pregnancy, local treatment of the infected sites is advised, and in that of concealed accidental hæmorrhage the author gives the impression that he has just failed to be courageous enough to exclude cæsarean section. No fewer than six different methods of treatment are described for the management of placenta prævia, and some of these, surely, are now discredited.

The assessment of contracted pelvis is essentially sound, and Caldwell and Molloy's classification is criticised. The estimate of the value, and lack of value, of external pelvimetry is definite and fair, but Professor Strachan's views on the results of trial of labour are gloomy. The student receives excellent instruction on the management of the occipito-

LACK OF PRECISION

Slackness in the use of words is a besetting sin of the modern doctor. The examinee who uses his mother-tongue to convey a precise meaning is a joy to the examiner, and unfortunately that joy comes but rarely. Lack of precision by the bedside, like the failure to use controls where this is possible, brings medicine into disrepute. One knows of instances where chemists, mathematicians, engineers, and astrophysicists despise the work of practising doctors. Their accusation against us is that although we live in an age of precision-instruments we shrink from the use of precise methods and constantly fail to define our meaning. That this is true can be seen by taking up current medical journals, let alone examination answer scripts. It is therefore not surprising that the examination candidate of today cannot be persuaded to describe the size of lesions in inches or centimetres.

The story is well known of two dermatologists as far apart as Frankfurt and Baltimore who were annoyed with each other because the one described certain lesions as being the size of a dime and the other the size of a pfennig. How can doctors be cured of comparing lesions in size to coins, fruits, and nuts? One frequently meets expressions such as "the size of a halfpenny, a threepenny bit, a grapefruit, an orange, a tangerine, a tomato, a nut, a hazel nut, an almond, a walnut, a coconut, a pea, a bean, a grape, or an olive." One would think men would have the sense to see that in any case there are several varieties of olive, many different sizes of tomato and tangerine, and at least two varieties of threepenny bit! The candidate who excelled at this type of description was he who described a lesion as the size of a large pea or a small bean. An examiner once took to task a man who said a tumour in a patient's neck was the size of an egg. "Well, what sort of an egg?"—"A hard-boiled egg, sir."

The use of meaningless expressions is quite common—"obviously poorly," "below par," "relaxed throat," "eyestrain," "sallow," "pale-looking," "toxic-looking." Loose terminology is rife. Thus a man will say "the patient has no temperature" when he means no fever, "the temperature chart was swinging" (remittent fever), "the patient has frequency of micturition" (increased frequency of micturition), "the patient has tubercular peritonitis" (tuberculous peritonitis), "he was given morphia" (morphine). In a viva a candidate will sometimes go to great trouble to avoid using precise terms such as fibrous ankylosis of a joint, maculo-papular pink eruption on the skin, left homonymous hemianopia, partial aphasia, granulocytopenia, or zoster virus.

Nobody suggests that examiners take off marks for all these petty mistakes. Obviously they must ignore such errors, otherwise they would never get through the dreary business of marking the papers in time for the next stage of the examination. But all this slackness leads sooner or later to loose thinking and to fundamental errors of principle. Thus it is common in clinical examinations for a man to say that he heard bronchial breathing over a certain point on the chest wall. When questioned about this he will admit that he has found no restricted movement, diminished percussion note, or alteration of voice sounds. The examiner swiftly discovers that he is not familiar with the physical signs of consolidation of the lung and that he is completely confused as to the difference between harsh vesicular breath sounds and bronchial breath sounds, and cannot define either of these. In the membership examination such a man fails, and richly deserves to fail. After all the membership is equivalent to an honours examination, and a man who displays such ignorance deserves to fail even in a pass examination like the Conjoint.

THE CLINICAL EXAMINATION

It is imperative that you should get through the clinicals in order to survive to the next stage of the examination. You just cannot afford to get any of the physical signs wrong.

It often happens that candidates invent signs to satisfy an imaginary diagnosis. Worse than this, a man imagines that he hears an aortic diastolic murmur and is quite content to diagnose aortic incompetence although there is no evidence of enlargement of the heart, no collapsing pulse, and no low diastolic blood-pressure. Many candidates fail to realise that the apex-beat of the heart may be found anywhere between the posterior axillary line on the left side and the nipple line on the right side. Cases of adults with long-standing fibroid lung are often misinterpreted by men who [illegible] to feel far enough out to the left for the apex. Innumerable candidates use the expression "[illegible] apex-beat," which is absurd because the apex-beat is defined as a point and therefore cannot be diffuse. Nor has the expression "diffuse apical impulse" any meaning. Candidates who use this expression [illegible] to convey that the apical impulse is thrusting, heaving, or forcible, and should say so.

Nearly every examinee will misdiagnose a case of polycystic kidneys, and hosts of men cannot define the difference between an enlarged kidney and an enlarged spleen. The number of men who can demonstrate they know how to examine the hip-joint, or any joint for that matter, is far too small. There is an idea in the minds of many candidates that a patient with joint disease, bone disease, or deformities of the spine or limbs belongs to surgery and not to medicine!

In the clinicals a candidate should never hedge. "The patient has a tendency to a hæmorrhagic rash"—either he has a hæmorrhagic rash or he has not. "There is the very slightest element of an aortic leak"—either the aortic valve leaks or it does not. "There is a certain sleepiness about the eyelids"—either the patient has ptosis oculi or he has not. If a man cannot make up his mind about these things surely he is not ready to take the exam. There is the story of the examiner (not a censor of course) who was a bully. He became quite impatient with an Indian candidate and barked at him: "Answer me, yes or no. Has this patient got mitral stenosis?" The gentleman from the East walked up to him until he was quite close and gave the answer in a whisper—"Perhaps."

The examinee who cannot handle with confidence a simple neurological case is clearly not ready for the examination. Yet few men have been properly taught how to elicit the plantar response. The region of the elicitation of this reflex is the outer border of the sole of the foot and the stimulus should always be applied [illegible] An extensor response may sometimes be obtained from this region when the inner border of the sole yields a flexor response. Examiners get tired of putting a [illegible] pencil through the erroneous expressions—"extensor Babinski sign," "his Babinski's are flexor," "the Babinski is plantar." What Babinski described was the extensor plantar response. It is far better therefore to use the expression "extensor plantar response," or else to say "positive Babinski reflex" or "up-going toe."

Candidates should have sufficient imagination to diagnose classical syndromes and diseases from what they have read. Supposing you have never seen a case, say, of hæmochromatosis, then you must be sufficiently familiar with its symptoms and signs to be able to recognise it. You will get a poor mark if you say such a patient has diabetes, fibrosis of the liver, and pigmentary changes which are in no sense correlated.

If you are not yet mature in your knowledge of medicine, you will commit yourself out of your own mouth

EVANS

HEPAMINO

the original proteolysed whole liver preparation for oral use supplies many essential metabolites for supplementing the normal dietary intake

Are you meeting with cases of malnutrition in your practice?

One ounce of Hepamino will supply

PROTEIN - - - - - -	one-half the total daily requirement
(providing the total daily requirement of essential amino acids.)	
NICOTINIC ACID - - - -	twice the total daily requirement
RIBOFLAVIN - - - - -	twice " " " "
FOLIC ACID - - - - -	twice " " " "
PANTOTHENIC ACID - - -	three times the total daily requirement
PYRIDOXIN - - - - -	one quarter " " " "
BIOTIN - - - - -	the total daily requirement
INOSITOL - - - - -	one eighth the total daily requirement

—and these are *immediately available* for biological utilization. Also present are iron and copper, vitamins B^{10} and B^{11}, purine and pyrimidine bodies and anti-macrocytic anæmia factors. Hepamino is issued as a dry, granular powder in containers of approximately 5 oz. at 15/-* each.

**Subject to professional discount.*

posterior position, and emphasis is rightly put on the time of interference. Whereas Kjelland's forceps do not get favourable mention, articles of such dubious value as the laminaria tent, the gum-elastic bougie, and the solid rubber bougie for use in the induction of abortion and labour are given a place.

The book concludes with a section on the casualties of childbirth, and a practical account, by Dr. Robert Drummond, of blood-transfusion.

The criticisms that can be offered are few and unimportant in relation to the vast bulk of the work, which received too little praise at the beginning of this review.

The Acute Infectious Fevers

ALEXANDER JOE, M.D., F.R.C.P.E., medical superintendent, City Hospital, Edinburgh. London: J. & A. Churchill. 1947. Pp. 276. 18*s*.

Dr. Joe's book, based on his experience as clinician and teacher in London and Edinburgh, is primarily intended to help the student and young doctor in solving the everyday problems posed by the common fevers. The author has succeeded in his aim: the clinical descriptions are clear, the discussions on diagnosis adequate, and the sections on prevention and treatment full. From the teaching aspect, the half-tone reproductions of photographs, as usual, are not uniformly successful: those portraying the pock diseases are very good, but those illustrating measles are but indifferent guides to the student. Dr. Joe is, throughout, conservative in his views and cautious in their expression: in scarlet fever most fever clinicians now deprecate the use of the douche-can for flushing the fauces, however gently, because of the danger of infecting the eustachian tube and thus the middle ear. While the reliability of the cough-plate in the diagnosis of pertussis is perhaps overestimated, the postnasal swab, of greater value in infants and young children who cannot coöperate, is not mentioned. But such are small points which do not detract from the merits of the book.

A Synopsis of Anæsthesia

J. ALFRED LEE, M.R.C.S., D.A., consultant anæsthetist, Southend General Hospital. Bristol: John Wright. 1947. Pp. 254. 12*s*. 6*d*.

A GREAT deal of work has gone into the preparation of this book; and although it is only of pocket size it contains a wider range of factual information than many textbooks of anæsthetics. Some statements will not be accepted everywhere. For instance, the maintenance of an adequate respiratory exchange with carbon dioxide and oxygen is given as the first treatment of "other convulsions"—the old term being retained in preference to the current one of convulsions during anæsthesia. A rise in blood-pressure and a heart-rate slowed to 50 is also regarded as a normal response to cyclopropane, while the use of such high concentrations as mentioned in connexion with cardiac arrhythmias has few advocates today. In the main, however, this book will be found to be a reliable source of reference and a quick means of revision.

A Textbook of Dietetics

(2nd ed.) L. S. P. DAVIDSON, M.D., F.R.C.P., professor of medicine, University of Edinburgh; I. A. ANDERSON, M.B., lecturer in clinical chemistry, University of Aberdeen. London: Hamish Hamilton Medical Books. 1947. Pp. 517. 21*s*.

THE first edition of this book in 1942 rapidly established it as one of the soundest and clearest treatises in this field. The second edition lives up to this reputation and the general practitioner and general physician will probably find it the most useful work on dietetics now in circulation. The fundamentals are treated with commendable clarity, and dietetic therapy with lusty common sense. Sections from the previous edition have been brought up to date and new sections have been added on parenteral therapy, the treatment of starvation, the use of folic acid, and food policy during the war. The authors pay an instructive tribute to the scientific guidance so largely responsible for the success of this policy. Professor Davidson might also have remarked that a wider appreciation of the teaching in this book would have saved the invalid rationing committee, of which he is a distinguished member, much unnecessary work, and also economised the time of our legislators.

The Child-bearing Years

C. SCOTT RUSSELL, M.A., F.R.C.S.E., M.R.C.O.G., assistant director, department of obstetrics and gynæcology, University of Manchester. Oxford: Blackwell. 1947. Pp. 88. 7*s*. 6*d*.

AMONG the educational books now available for the lay woman it is pleasant to find one of outstanding merit and suitability. Mr. Scott Russell offers the woman of average education a good survey of the physiology of childbearing, menstruation, and the menopause. Contained in these chapters is also a [illegible] description of relevant pathological conditions, and he must be congratulated on his skill in describing these without playing into the anxiety of his reader. [illegible] of the sections contain just the type of information women require, and this is given in a direct and way.

It is perhaps a pity that in the chapter on breast feeding the emotional advantages to mother and child receive no mention. For both mother and child breast-feeding is invaluable as a means of education in intimacy and loving. With natural easy mothers suckling is indulged in simply; but the neurotic woman may all too easily lose this natural way of breaking down the barriers if these facts are not pointed out to her.

An Introduction to Bacteriological Chemistry

(2nd ed.) C. G. ANDERSON, PH.D., DIP.BACT., formerly Lewis Cameron teaching fellow, University of Edinburgh. Edinburgh: E. & S. Livingstone. 1946. Pp. 500. [illegible]

ALL living cells have the same basal biochemistry, and for this reason bacteria can be used for the rapid and economical assay of a wide range of biologically important substances such as amino-acids and vitamins. Bacterial enzymes are capable of performing almost every possible biochemical reaction, and we now know that several bacterial toxins, such as the α-toxin of *Clostridium welchii*, are enzymes. These are among the many reasons why [illegible] students of bacteriology should know something of the chemistry of micro-organisms. The present edition of this excellent book contains a new chapter on the antibiotics and a fresh presentation of the facts about growth factors. General subjects such as enzymes and colloids and adsorption are followed by a much larger section on the metabolic habits of bacteria, and finally there is a clear explanation of modern views on immunochemistry. It should be said that only an elementary knowledge of organic chemistry is needed to find the way in this expanding field of study.

Human Embryology

BRADLEY M. PATTEN, professor of anatomy, University of Michigan. London: J. & A. Churchill. 1946. Pp. [illegible] 45*s*.

THIS is one of the best textbooks on human embryology produced in recent years. Original in style, arrangement and illustration, it is unusually attractive to read and entirely up to date. The illustrations are well produced and clarify those aspects of development which the student often finds most difficult. The sections dealing with the functional significance of developing structures are somewhat of an innovation, though perhaps unnecessarily detailed in the case of the central nervous system. The story of development is carried well into postnatal life, and developmental defects receive detailed treatment. It is pleasant to see the sections on development of general tissues, such as bone and muscle, placed early in the book, instead of being relegated to an odd chapter at the end as so commonly happens. A few points for criticism no doubt arise—e.g., no reference is made to osteoclasts in bone growth; the magnification of many of the photomicrographs and illustrations of reconstruction models is not stated; and there are a few loose phrases, such as the description of the ventral nucleus of the thalamus as "a conscious and relay centre." But these are small blemishes in a book of exceptional originality and accurate detail.

THE LANCET

NDON: SATURDAY, AUGUST 30, 1947

Sometime, Never?

those who returned from the first world war study of medicine, some did well, and a few ntly; but many found it hard to readapt elves to academic life, and either abandoned ine or qualified late. This time it is different: om the Forces have delighted their teachers with zeal and grasp of essentials; indeed some who previously the despair of their mentors have ently turned over a new leaf. No single reason ins the difference, but it may be largely due to circumstances—improved selection, the changed cter of Service life, and the grim times in which ve. Of recent years the medical schools have to recognise that students are best selected not y by examination but also by their background, nality, and interests; and this lesson has been ed effectively to the returning Serviceman. dly, the war of 1939–45 being largely mechanised, were continuously schooled in scientific or scientific subjects and never lost the knack of ing; and at the same time they were not subd to the unremitting and disturbing strain of h-warfare which their fathers suffered. Finally, er during nor after the late war was there any aganda along the lines of "a land fit for heroes"; in the Forces never lost sight of the fact that t they wanted they must work for; and if, on return, a reminder was needed they found it ur national poverty and the continued interonal uncertainty. When they began their studies ervice students often found that they had lost "blotting-paper" memory which is so well rded in examinations; but they have brought to r work maturity and judgment, and a determinato make the most of their opportunity. In some ols—partly because of their application and partly use many are married—they have not engaged h in outside interests; while in others their ence has shifted the centre of student social vities from athletics to more staid recreations such usic and drama. The younger student is gaining h from the older.

he inference for peace-time is not certain. Most lical educators favour a break between school and versity, which they say promotes the maturity ential if the student is to benefit fully from his sequent training. It may be reasoned, too, that interval provides a much-needed rest before rting on the last six years or so of an education t has already been proceeding for ten years or re. And again it may be argued that since the dical student and doctor meet people principally patients, candidates for medicine require an erval in which they can get to know healthy manity. These are all valid contentions, and ough such a break can be bought only at the price reducing the working life of each doctor [1] there will a case for insisting on it when the shortage becomes less acute. At present it is scarcely a matter of choice: during the next few years, the medical schools' preoccupation with ex-Service students will necessitate the deferment of many younger men, who will thus first enter the Forces. But it would be a mistake to feel confident that during their service these youngsters will develop the same sturdy qualities as did the war-time Serviceman. During the war our soldiers, sailors, and airmen were sustained and united by a clear purpose, for whose achievement they submitted to a discipline which was often largely self-imposed and which now rewards those who returned. But the incentive of victory has gone, and no other strong incentive has taken its place. Even among the men who had done the fighting, the end of the war brought schism and bewilderment in place of unity and determination. And if this happened among those who had shared a common experience and reached a common goal, it is still more apparent among the young men who, having had no hand in the war, are thrust direct into the demoralising environment that is the usual portion of any occupying force.

THE SCHOOLS' PART

Doubt about the future is apt to be a grave disability; and during their period of national service men with a planned career ahead of them may be expected to fare better than those with none. Here then we should welcome the enlightened practice of the Liverpool school in promising admission after deferment and national service to selected candidates, subject to satisfactory conduct.

In considering how best to help these young men, the schools might also overhaul their system of selection. At present they can accept only between a tenth and a quarter of all applicants; but many of these candidates, uncertain of acceptance at any, apply to several, and sometimes indeed to all, schools. For the schools this means that, after careful deliberation, a student is selected who may later announce that he has been offered a place elsewhere which he prefers. For the candidates these multiple applications involve loss of time and sometimes the strain of sitting examinations imposed by the individual schools. The Royal Free Hospital school of medicine has decided to abolish its entrance examination, and others may do the same; but those schools that value an entrance examination might, like the public schools, at least accept a common one. The confusion caused by multiple applications could be ended by having a central register, on which all intending medical students would enter their names. A year ago we suggested [2] that the control of this register should be in the hands of a standing committee of deans, representing every school of medicine; and we return to the proposal in the belief that such a committee could be useful in more ways than one.

Except for the management of the register, this body should, we suggest, be purely advisory and consultative. In the first place it could deal effectively with some of the problems confronting the individual schools. For example it is feared that the increase in Treasury contributions, through the University Grants Committee, may presage interference with the running of the schools; and the committee would be well placed to detect and ward off any attempts in this

be the promotion and advancement of research cardiac rheumatism in childhood. Not far away, is Stoke Mandeville, with the Ministry of Pensions ital for paraplegics. Ashridge itself is no longer a ital, but it would be a convenient place for a ring of medical men or hospital people, such as a al board or newly constituted board of governors eaching hospital. Here they could get to know nother in pleasant *surroundings*.

A CAMP FOR CRIPPLED PEOPLE

PING for pleasure is usually regarded as a pursuit e active. At "Woodlarks," near Farnham, it has shown that even severely disabled people can the chief pleasures of camping—the open-air life, s, camp-fire parties, nights under canvas, and good e food. This camp is specially planned for them, ts success depends on the work of large numbers of g helpers. As the annual report notes: "If there oo few they become fully occupied with the chores he camp and have neither the time nor the ration to do all that might be done."

a camp held in August there were 25 crippled and women and 45 voluntary helpers, 22 of whom rangers in the Girl Guide movement. The cripples very severely handicapped, most of them chair unable to walk at all, and one at least in a spinal age. Many of them spend the rest of their year mes and institutions for helpless cripples, their lives wed to the tiny orbit of the ward's day, their minds verished by lack of any sort of stimulus. This has become for many of them the chief event of year, with an effect long outlasting the ten days lly spent at Woodlarks. Friendships are made here carried on by correspondence until they can be ved again, new interest in country things can be loped by reading during the winter, and, perhaps important of all, since they are encouraged to themselves, many cripples learn to increase their e of movement and physical power. Two, at least, had not walked before learned to stand and take their steps in the camp.

oodlarks was founded in 1930 by Lieut.-Colonel R. Strover and his wife, who with their children he moving spirits in running and maintaining the . The large site lies off a wooded ferny hillside g a fine stretch of country. Paths and roads, made ly by rover Scouts, wind through the woods and will y take wheel chairs (plenty are kept in stock) and l carriages. The crippled campers can thus be taken untry excursions and on expeditions to neighbouring ens, can go blackberrying, and can watch birds and als. A swimming-bath, made from discarded tic water" tanks, is in the process of construction. ds of Woodlarks go down to spend strenuous week- in welding and riveting, and the result promises to ery good. Many cripples are able to swim, and more joy bathing. In the evening campers join in songs, petitions, and games round the fire, or if the weather t hold parties indoors.

he buildings are simple, solidly built in brick with windows. A large dormitory, able to take 25 les who have not gained their doctors' permission eep in tents, has folding windows down the whole h of one side. This room and the dining-room have good hearths. The lavatory block is specially designed. In the water-closets pans of various and heights have been fitted, and each is flanked pair of wooden arms to help the user to rise from the Each water-closet has a wide door and is large gh to allow a wheel chair to be brought in and ed. Ample baths, wash-basins, and hot water are ided. The first aid room, with a bed for casualties or suspected cases of infectious disease, is put in charge of a nurse or doctor among the helpers.

The kitchen is outdoors with a pent-house over it to protect the fire from rain; for the cooking is done as it should be, over an open fire. This is built in a long narrow brick trough, across which iron rods are laid to support the cooking-pots.

Ten-day camps are run steadily from May to September, camps for boys alternating with camps for girls. The report emphasises that the camp is run for *severely* handicapped people, and a visit is enough to show that this is no polite boast. But strangely enough it is always easier to persuade badly crippled girls to come than badly crippled boys. Crippled boys have often become too dependent on their womenfolk, and fear to trust themselves to an all-male camp, though the helpers are able and practised: the girls, of course, can count on the care of women; but they seem in any case more enterprising. Family doctors, it is found, are often over-cautious about advising parents to send their crippled children. A doctor's letter saying "I don't think he is too severely disabled to come to camp" generally precedes the arrival of someone almost too lightly handicapped to be accepted. The best testimonial to the value of the camp comes from the cripples themselves, who, once they have visited it, return year after year.

Before the war Colonel and Mrs. Strover used to run toy-making classes at the camp once a week for neighbouring cripples; and the toys made were exceptional in design and workmanship. Now they hope to extend this plan by running a residential training course in toy-making. Two gardeners' cottages on the camp site have been bought to house the staff and those in training, and a large airy workshop is to be built; but funds are needed. Woodlarks is built on voluntary subscriptions and gets no grants at present: it is too small to qualify for some, and the training scheme, being still unproven, cannot as yet claim others. Nevertheless it is doing remarkable work, the value of which doctors in charge of institutions for the crippled can well appreciate. Those who wish to support it should write to the hon. treasurer, Woodlarks Camp Site Trust, Farnham, Surrey.

FAREWELL TO THE I.M.S.

THE Indian Medical Service was formally dissolved on Aug. 14, and in the letter of retrospect and farewell which he has sent to every officer Lieut.-General R. Hay, the director-general, summarises the history of the service since 1612 when John Woodall was appointed the first surgeon-general of the East India Company. "As I pen these words to you," he writes, "the service is being wound up and its members are dispersing. Some of us will find new careers in the service of the Crown, in the health services at home, and elsewhere in the British Commonwealth. We know that their service here has fitted them to contribute generously to their new tasks. Our Indian members will be completely absorbed, with some of their British colleagues, in the two new Dominions. To them in their new sphere and to those who will work with them, we hand on our torch."

Prof. E. C. DODDS, F.R.S., has been elected master of the Society of Apothecaries of London.

Prof. N. HAMILTON FAIRLEY, F.R.S., and Prof. J. H. GADDUM, F.R.S., have been appointed members of the Medical Research Council from Oct. 1.

Sir THOMAS CAREY EVANS, former medical superintendent of the Hammersmith Hospital, died on Aug. 25 at his home in Wales. We also regret to record the death on Aug. 16 of Dr. ELLIOTT C. CUTLER, professor of surgery at Harvard and a companion-in-arms of British surgeons during two wars.

direction. Then again the effort at some schools to increase the output of graduates in anticipation of increased demands under the National Health Service Act is frustrated by refusal of requests for beds and buildings; here, too, the case could be put with weight by the committee. But perhaps the most valuable of all its functions would be the pooling of experience in teaching. Medicine is compounded of many subjects, whose importance is assessed differently at each school. Nothing would more certainly damn medical education to a uniform low level than ironing out these differences by ukase: the schools must be free to organise their curricula according to local taste and talent, subject only to reasonable minimum standards. But the negative duties of the General Medical Council might well be balanced at the positive pole by a body which set itself to pick out what is best in each school and bring it to the attention of others. In the past year different schools have set up new departments in social medicine, industrial medicine, medical statistics, rheumatology, and other special subjects. As is shown in the article by Professor ARNOTT and his colleagues which appears on another page, at least one of these departments can stake a claim to a regular place in student training. Experience should be shared as it grows; and a council of deans, more comprehensive and with more official st than the committees and groups already in exist is the proper body for the exchange. It might that to place this burden on such a council is u sary, since each school must surely learn uno of its neighbours' progress. Unhappily this is n Though each school is eager to make the mo its own resources, few have had, or have taken, opportunity of measuring their achievement a others'. Deans are already overworked in ad tering their own schools and in fulfilling duties re to their chairs. This has been acknowledged in schools by the appointment of a full-time de administrative officer, or of a subdean, or by st rotas in which each professor bears the burd deanship in turn; and, if the proposed commi to be virile and active, deans everywhere must ha help of whole-time officers to relieve them of ro

The duties of the medical schools in t students are, broadly, to pick the right men women; *to train them as fully* as possible; and supply the country with suitable graduates in required numbers. In each of these function schools can help themselves and each other sending their representatives to meet round committee table.

STUDENT HEALTH

PILOT surveys of students at Oxford, Cambridge, Sheffield, and Bristol have revealed a disturbingly large number of minor and remediable disabilities and some serious illness among them. At a conference on student health in British universities and medical schools, arranged by the Nuffield Foundation and held at Oxford on July 8 and 9, students were reported to suffer mainly from minor defects of eyes and teeth, and mild skin disorders. Some needed advice on the management of cardiac, digestive, or orthopædic conditions; and 15–30% had minor anxieties most of which were relieved by explanation and reassurance. In the Oxford survey, 15% of all students were deemed to need treatment before the end of term, and another 40% needed treatment which could safely be postponed to the vacation. Routine X-ray examinations of the chest were made at the universities of Oxford, Cambridge, Bristol, Wales, and Belfast, and at University College, London, and some of the London medical schools. In every case examples of active tuberculosis and openly infectious pulmonary tuberculosis were found, usually at a stage early enough to give good prospects of recovery. It was noted at the conference that though isolation of infectious cases from a closed or partly closed community is an essential public-health measure, at present a medical officer of health may know of student cases without having permission to inform the college authorities.

Studies of social conditions affecting the health of students in Edinburgh, Leeds, and Liverpool brought complaints of the scarcity of accommodation and the poor quality of the midday meal. Prof. F. A. E. Crew, F.R.S., reported that, at Edinburgh, 35% of men and 42% of women students wore glasses. Four days' illness a year per student might be expected; and a quarter of the men and nearly a third of the women had an illness last year which caused them to go to a doctor; the average duration of these illnesses was 16 days. He found that 74% of medical students and 64% of all other students were in favour of compulsory medical examination after admission to the university. The principle of compulsory health examination is fully accepted in the United States, and routine examinations of this kind ensure that all discoverable handicaps can be treated, and that conditions like pulmonary tu losis which endanger both the patient and his comp do not go undetected. Information gained from compulsory examinations show health and se tendencies accurately, and make possible compa studies in different universities.

Several universities which already have st health services contributed their experience. It agreed that sick-bays in colleges and hostels, attended a whole-time or part-time nurse, are needed; and in or associated with a hospital, where cases can be investigated.

Various estimates, ranging from 450 to 1000, were of the number of students whom a single whole- physician can be expected to examine. He needs tarial help and X-ray facilities. From July, 194 cost of treatment will be covered under the Nat Health Service. The conference resolved that a student health service should be provided for all unive students, and that provisions for the care of sick stu should be improved. Every university, it was should appoint at least one whole-time physician, where necessary other whole-time or part-time d to help him. The physician should have adeq accommodation, equipment, and secretarial and nu help. A subcommittee is to consider a design for standard record card. A further conference is pla for 1949, and in the meantime an interim coördin committee has been appointed, the secretary b Dr. R. W. Parnell, of the Institute of Social Medic *10, Parks Road, Oxford.*

ASHRIDGE

A CORRESPONDENT draws attention to the amenit Ashridge Park and its advantages as a meeting No medical body, he says, has yet made use of it in same way as the Magistrates' Association or the Nati Council of Social Service. Yet the house is well ada for the purpose of conferences, and the grounds famous. Standing on the borders of Hertfordshire Bucks, Ashridge is now owned by the National Tr which is doing so much to preserve the beautie England. Near at hand is Cliveden, with the Cana Red Cross Memorial Hospital at Taplow, whose spe

:iven the research and the men to carry it out,
s no reason why the business of feeding populations
not ultimately become a rational science and a
:able branch of preventive medicine.

THE ACADEMIC PATH

ING had good luck, good health, and good friends,
become (as I wished) a whole-time clinical professor.
e try to give some account of the path I travelled.
n the faculties of science and medicine of an
t and populous university, I secured the honours
s which convention requires in mentors. More
:ant, I gained the absorbing and sustained interest
converts apparent drudgery into a continual joy
leasure. Most medical men work long hours com-
with the generality of mankind, and this is certainly
f those who follow the academic pathway. (I have
) meet a senior medical teacher who does not
ally spend most of his working hours in professional
and who does not take home with him at night
t the weekends a formidable assignment of home-
) But much of the work is creative in the sense
t consists in the devising of a new administrative
aching scheme, the evaluation and analysis of
ch data, or the writing of a monograph or article.
vever, the secret of diligence is interest; if one really
s work, it ceases to be an effort and becomes relaxa-
Boredom is perhaps the most exhausting circum-
: in human affairs; indeed, a cynic once said that the
aim of life was to pass the time between birth and
. Viewed from this angle academic medicine is
t satisfying career in that it provides an infinitude
ties, problems, and opportunities—all interesting.
ps the most important function of university
tion is to teach what is *not known*—that is, to
:ate lively curiosity into the minds of its graduates,
in them not only to apply knowledge but to be ever
ful for new knowledge, and to be ready to discard
nend the old in the light of the new.

all-too-brief period in general practice, partly in a
erous rural area and partly in a mining area during
lepression, afforded some insight into the daily
ems of the general practitioner. There then followed
as house-surgeon and house-physician. The vital
was taken when I was appointed to a registrarship
teaching hospital. Nowadays many of these posts
ull-time and carry a bare subsistence stipend, but
at time they were purely honorary and a living was
in a variety of ways—partly by coaching, and
y by work in pathology with research scholarships.
latter activity constitutes a most essential part of
raining of the academic clinician. Several years of
time work in one of the basic sciences, such as
iology, biochemistry, or pathology, mould an attitude
ind and an approach to clinical problems without
h sound teaching is probably impossible. For me
work was partly routine but mostly research: in
l measure productive, in larger measure unproductive
nat no publications ensued; but all beneficent in
it taught techniques of observation and measuring,
practice in the statistical treatment of data and
ction therefrom, and, above all, inculcated the urge
find out." Coaching for 3rd M.B., for "Finals," and
lembership, both individually and in classes, provided
tice in the art of exposition and a working stock of
al data; while the much-needed cash-returns operated
sensitive index of one's market value as a teacher.

that time there were few whole-time clinical
intments, and further advancement lay along the
of election to the honorary staff of a teaching
ital and the development of consulting practice—a
pect satisfying enough but giving all-too-little time
:he more elaborate forms of research. Into all this
e war, altering completely, as it did for all of us, the
r of life. A prior undertaking relieved me of any
sions; immediate mobilisation with early posting
oreign service followed. In retrospect it is possible
ealise that war service had a certain educative value.
rought the opportunity to practise tropical medicine,
the necessity, in the absence of better qualified men,
lo one's best in infectious diseases, psychological
licine, dermatology, and, in times of battle, in
sthetics and even in surgery. Emotionally it certainly extended the range of experience; it brought the bitterness of long exile, the crises of acute physical fear, the communal joy of military success, and finally the harrowing sight of a proud enemy beaten to his knees, his cities reduced to rubble. Educationally war brought peculiar opportunities in that I shared extensively in the training of medical specialists, the basis of which was a 3–6 months' course of instruction in a military hospital.

After demobilisation I had a generous welcome on returning to my old school; and some months later I was elected to a whole-time chair, where my duties comprise (to paraphrase the articles of appointment) conduct and general arrangement of teaching in medicine; care of patients in the teaching hospital; and the stimulation, direction, and personal prosecution of research. These responsibilities have been greatly lightened by the friendly and sustained help of new colleagues.

Mine is a story devoid of the unusual or the glamorous but, of its kind, typical enough to illustrate one of the prospects in the wide ambit of medicine.

W. M. A.

IN A COUNTRY PRACTICE

TURNING over the pages of the illustrated weekly before putting it in the waiting-room, I found a reproduction of Sir Luke Fildes's *The Doctor*. The caption proclaimed that "this celebrated picture is being used by the United States authorities for a new issue of stamps"; so our American cousins must still have a warm heart for the general practitioner of fifty years ago. Today, especially in the urban areas, his work is weighted with monotony, but gone are the days when most of our profession are engaged in purely clinical work.

After ten years in a country-town practice I feel justified in replying to those who were fellow students and who had said I would be just a jack-of-all-trades. It was well worth while to do a string of house-appointments so as to be suitably prepared for the kaleidoscope of rural practice. There is still charm in the variety of the work, not only in its clinical aspect but also in the versatility needed in dealing with the domestic sphere—from the terse orders to the half-witted stonebreaker to the advice proffered to the elderly dowager; from the urgent emergency of the perforated enteric to the patient encouragement of the hemiplegic convalescent; from the recipe for beef-tea to the supervision of a penicillin infusion.

The major part of the work is plain general practice; the town is small, and two-thirds of the patients are beyond the outskirts. At hand we have a cottage-hospital where two of us perform such surgery as can be accomplished without a pathologist and radiologist in daily attendance. Our half-dozen colleagues are all members of the hospital staff and care for their own patients while warded. Thus we each attend our own more seriously ill patients unless they require special investigation at a larger hospital. The interest from this uninterrupted supervision is a great stimulus to keep up-to-date. This being a very rural area, most of the exanthemata are nursed at home; but the fever hospital is resorted to when home conditions are questionable.

There is a privately run maternity home in the town, where those who lack the necessary help at home can be confined. A personal bias to home nursing means that most cases are still attended in their own beds, with the conscientious help of the Queen's nurse, or perhaps of one from the "Co-op." The professional bond under such conditions is much firmer than where the child is manipulated in the antenatal and delivered in the maternity department and weighed in the infant-welfare clinic, before being passed on to the education authority for medical supervision. The town has all these services, but they are not largely used except of economic necessity.

Consultants' advice may be obtained through the local authority, or at the neighbouring general hospital, or at the patients' private whim. There has been no occasion when patients have not had the chance of the best advice locally or more distantly; if they had their doubts, they presumably changed their doctor. The difficulty of transporting urgent pathological specimens is now more easily solved; many times a full round has been interrupted by a thirty-mile journey with a culture incubating in a waistcoat pocket.

UP OTHER STREETS

Some start their medical training with a definite aim. These, who are not many, are mostly men and wome career is already decided—for example, the pure scientist who has found that his researches demand more than a acquaintanceship with medicine, and the barrister who seeks to specialise in medical cases at the bar. For qualification brings a bewildering choice of paths. Which to take? We print below articles by four contributors who answered the question to their own satisfaction, and so have at least warded off the boredom which one of them stig as "perhaps the most exhausting circumstance in human affairs."

PERIPATETIC NUTRITIONIST

A MEDICAL specialist in nutrition hates to be called a "nutritionist" in case he is mistaken for someone trying to sell vitamin capsules or breakfast cereals. He likes to think of himself as engaged in a branch of preventive medicine, although as a rule he has no special qualifications in public health. Broadly, his job is to try to find answers to the recurrent question "Are people getting enough to eat?" This question has come up repeatedly and urgently in many places, during and since the war. Consequently there has been a good deal of travel to be done by one, such as myself, working in this specialty. Sometimes the journeys have been far from dull.

I remember struggling in the blackout with a large belt-driven centrifuge of antique design, attempting to get a foothold on a jam-packed night train to Scotland . . .

I remember a philosophic discussion in the Conservative club of a Welsh mining town with the Socialist city fathers . . .

On Christmas Eve, in convoy off Sicily, the chief engineer hung a stocking on his cabin door, hopefully including an empty bottle of Johnnie Walker . . .

Down the long dusty road from Teheran to the sea we ran head-on into a whole tribe of migrating Kurds—a pandemonium of sheep, goats, and children, mingled with the shrill cries of women . . .

At the U.S. Army airfield on the Persian Gulf (temperature 105°F), I asked a pilot, "Where are you heading?" "Cairo." "Any room?" "Why sure, climb right in" . . .

Crawling along on the night train to Marseilles, in the last winter of the war, my Canadian colleague heated up a can of C rations and afterwards opened it, spraying everything with pork and beans . . .

Later there were frequent flights about Europe, mostly in Dakotas of varying decrepitude; on one such trip a kindly major-general spent the time showing two small children how to vomit into paper bags . . .

Some views from the air are not easily forgotten: the Bavarian Alps, Corsica, the Bay of Naples, and the mountains of the Peloponnese . . .

On the reconstructed narrow-gauge railway from Sarajevo to Belgrade the train wound painfully up the mountain to a point where there was a sheer drop of a thousand feet down to the Drina River; here the ticket-inspector apologised to us in French: "We have to go slowly here; track still bad" . . .

On a ploughed field outside Budapest we waited, sheltering from the rain, under the wing of the R.A.F. plane that had brought us in. After an hour or so, two Russian N.C.O.'s showed up, with a *supposed list of passengers*; this was solemnly read over in Russian. To be on the safe side, all the passengers answered "Yes" in unison, as each name was called. The inspectorate seemed amused by this and we were allowed to depart for the city without further formalities . . .

Then there was a nightmarish voyage to the States on the *Queen Mary*, with 2000 G.I. brides . . .

This job has a lighter side which compensates for some longish spells at an office desk.

In fact, the job involves a good deal of office work. To arrive at a fair estimate of a community's nutritional state it is necessary to study its food consumption. The current ration scales may tell you a great deal or nothing, according to the extent of the free, grey, and black markets. Certainly if the overall food-supplies provide a retail average of 2500 calories a head daily, or more, it is most unlikely that there will be anything seriously wrong; just as the presence of a measurable amount of vitamin C in the plasma excludes the diagnosis of scurvy. Then there are often long lists of food imports, to be worked out in terms of nutrients per head of population daily. A reliable dietitian is an invaluable help with this. In point of fact it is quite entertaining to divide so many thousand tons of wheat by so many million people, and find out how many calories should get. Just occasionally one is rewarded by a displaced 0 in the previous calculations of other But such armchair analysis does not answer the question, "How is the nutritional health of the pe The only way to find this out is to go and look for

Ideally, the way to set about investigating the of a population is to move in with a team, comp mobile laboratory, technicians, statisticians, di and so on. First of all an adequate sample of the tion is selected by scientific sampling methods: the next thing is to collect detailed medical, bioch social, and economic data on all the individuals prising the sample. This method is fine for the l study of nutrition in stable communities in peace but it was difficult under the confused conditions often confronted UNRRA in post-war Europe. For thing, elaborate data take time to collect and ever to analyse; when eventually they get to be writte the situation has probably changed and their is academic. In any case, we could never have at anything of this kind, if only for the reason that were never enough medical officers trained in nu to cover the whole vast field of UNRRA's operatio Europe.

But one medical officer, on a temporary visit to country, can learn a surprising amount about the state of nutritional health. First, it is worth lis to the doctors on the spot; they may know the death-rate and infant-mortality rate. Have they any famine-œdema or scurvy lately? Someone probably thought of collecting repeated weight m ments on children in schools or feeding centres next step is to look for the worst—in hospitals, ages, schools in slum areas, or devastated villages. that it is a good thing to examine as many peop different kinds, as time and opportunity will allow. quick inspection of the face, eyes, mouth, and extr will reveal most of the clinical signs that are apt to associated with underfeeding and malnutrition. method is not scientific and does not pretend to be it was sufficient to provide rapid answers to m the nutritional questions which previously had surrounded by a fog of uncertainty in London Washington.

Last year, in the months before the harvest, there a potential food crisis in Europe. The grim prospect famine in parts of Greece, western Yugoslavia, and perhaps parts of Poland seemed a definite pos in the early spring of 1946. But, thanks to the volume of foodstuffs imported by UNRRA, these fa did not occur. In fact, in the UNRRA-aided co generally the state of nutrition as we observed it, th often tragic enough, was nevertheless better than had dared to hope. I encountered real famine only —at Belsen concentration-camp. There I had the p lege of being associated with ninety-six medical stu from the London hospitals. In any similar ch desperate situation, I would always ask for the help a hundred students rather than a hundred doctors.

Nutrition as an established part of public-he practice is still in its infancy. Unfortunately it lacks precise methods of epidemiology; one cannot comp the total number of underfed persons in a commun *All that can be said is that some are obviously* well others obviously malnourished or underfed; but th is usually a very large intermediate group, whose nu tional status cannot be defined precisely with exis methods. More research is needed to develop be techniques for assessing this group; more must learned about the true nutritional needs of different of community in different climates; better ways estimating indigenous food production ar

Medical Schools

)XFORD UNIVERSITY the number of new students
icted by decree; the number during the coming
as been fixed at 55 men and 10 women, but
rice men and women are admitted over and above
numbers. Students without war service who
ılated after the end of Trinity Term, 1946, will
ger qualify for the B.A. degree by passing the
M. examination. Instead, they will be required
the second public examination; the course for
amination normally taken by medical students
final honour school of animal physiology. The
school is to become a permanent feature at
, so that students may qualify either at the
ffe Infirmary or by transferring to a teaching
al in London or elsewhere. The clinical adminis-
and social centre is being established in Osler
, which is beside the infirmary.

after the beginning of the late war the UNIVERSITY
MBRIDGE shortened the minimum period of pre-
l study from three to two years and suspended the
tion requiring candidates for a medical degree to
eached an honours standard in a tripos examina-
These war-time concessions have now been with-
. The distinctive character, and indeed the
tion, of the Cambridge school rests on the oppor-
provided to students by the natural sciences
to acquire a sound knowledge of the branches of
al science on which clinical practice must be based.
staff of the department of medicine has been
gthened by the establishment of a readership. A
rtment of experimental medicine was formed in
; and last year an appointment was made to the
chair of radiotherapeutics. A department or sub-
rtment of human ecology is planned; and it is
cted that further departments in various branches
linical science will be established. The School of
cal Research and Postgraduate Training, which
been considerably developed during the past year,
depend for success on close coöperation between
university and Addenbrooke's Hospital; and the
anism for this has been provided by the formation
medical school council, on which the university, the
ral committee, and the honorary staff of the hospital
represented. Since 1939 a unit or branch of the
lic Health Laboratory Service, established by the
ical Research Council for the advancement of know-
e of epidemic diseases, has been quartered in the
rtment of pathology. Proposals have been approved
he university and by the M.R.C. for the incorporation
he senior members of the staff of the Public Health
oratory Service with the staff of the department
pathology, to the great advantage of research
teaching in bacteriology. Readerships have been
blished in bacteriology and in morbid histology.

London Schools

ONDON UNIVERSITY bears a different relation to its
lical faculty from other universities: whereas they
e one school of medicine each, London has the twelve
nomous schools of the teaching hospitals, as well as
versity, King's, and Queen Mary Colleges, all of which
medical students for some part of the course. In
ition, external students of the university may take
r clinical training at the West London Hospital, which
ıot a school of the university. Up till now, apart
n the Royal Free Hospital, which has accepted
nen only, the only London schools to train women have
n Charing Cross, King's College, University College,
West London, and—since 1945—St. George's hos-
ls. From the beginning of the new session, however,
hitherto exclusively male schools are to accept 15%
women students, while the Royal Free Hospital is to
e 15% of men.

At UNIVERSITY COLLEGE the faculty of medical sciences
medical and preclinical years) has now regained its territory, occupied for some years by Government departments, and work and accommodation are on about the same footing as in 1939. Candidates for entry to first and second-year studies are selected by examination early in January. Entry to the premedical course is restricted by lack of accommodation in the departments of the faculty of science, and the number of women students is restricted to a quota of one to about forty men. The faculty gives every encouragement to medical students who wish also to take degrees in the faculty of science, and offers scholarships to that end for a further year of study, leading to a B.SC. (special) degree in anatomy or physiology after passing the 2nd M.B. examination. As in some other schools there is increasing coördination between the various departments, so that the student is presented with a more homogeneous body of knowledge than in the past.

KING'S COLLEGE is one of the largest schools for medical studies in London, supplying students to three hospitals—King's College Hospital, St. George's, and Westminster. Arrangements are made by which patients attend the college for clinical demonstrations in applied physiology, by clinicians. The students' hostel has been reopened.

The arrangements made by the joint committee of QUEEN MARY'S COLLEGE and the London Hospital medical college are working efficiently; and now that the college holds its own special internal 1st M.B. examination the teaching subcommittee has organised the instruction in physics, chemistry, and botany to fit in closely with preclinical teaching. All available places are taken by London Hospital men and women; during the 1946–47 session 56 1st M.B. and 20 premedical (conjoint) students passed through the departments.

Like many other London schools, UNIVERSITY COLLEGE HOSPITAL medical school has been busy drafting a charter in preparation for its legal separation from the hospital. Close coöperation will of course be maintained, just as in the past the school has retained a close voluntary association with the medical faculty of University College. This association has lately been strengthened by the appointment of a joint lecturer in applied pharmacology, with a firm footing in both institutions, and also by coöperation in the difficult work of selecting students. The medical school accepts all students who complete their preclinical university course at University College. The school also keeps vacancies for students from other universities who wish to undergo their clinical training in London. Each year 14 women are to be admitted—10 from University College and 4 from Oxford or Cambridge; this is 2 more than in the past. Additional clinical material will, it is hoped, be obtained by "assimilating" other hospitals in the neighbourhood. Teaching is being increasingly coördinated, and discussions are held between members of the various clinical departments as part of the routine clinical instruction. The three whole-time professors of clinical subjects are now responsible for the coördination of teaching in the hospital as well as in the school. The students' hostel has been reopened and extended, so that the greater part of a year's entry can now be housed on the spot; the hostel includes separate houses for women students.

In order to accommodate as many ex-Service students as possible ST. BARTHOLOMEW'S HOSPITAL medical college is still accepting about 20% more than the likely intake at which it aims when the college is fully rebuilt. Despite repairs to the buildings, which were severely damaged in the war, there is some overcrowding. Plans for permanent rebuilding include a residential hostel. A feature of the teaching is the opportunity given to students to study cases for themselves rather than first hearing the opinions of others. Opportunities for studying patients in their own environment are being developed, with emphasis on the influence of environment on disease, and on the means of maintaining full health.

The peace-time emergencies in the country are those of the farm, the river, and the road. Pliers have been needed before now to rescue a fractured sternum from a truss of hay in a baling machine; and winter storms have necessitated wading to the waist in the fast-flowing floods to reach a pneumonia.

The interludes allow time for professional meditation. Why had we to await the outbreak of war to prove the merits of black-currant tea? Should not the cottager's faith in the raspberry leaf at her confinement have suggested an earlier search for the active principle? While many country remedies are apparently useless, others are not, though they have yet to reveal their secrets to the biochemist. How long was the submerged root of the willow gathered before the synthesis of the salicylates? The little girl fondling her pet lamb had her peculiar "stye" elucidated when our veterinary neighbour told of attending a ewe with vaccine. Medicine in such surroundings recalls that nature is still mistress of much that we claim to rule. You need to be abreast of recent work, though the incentive can readily be lost in the placid environment: perhaps it was only the daily press that helped me to spot the early poliomyelitis the other evening. You need a fairly large medical library at your elbow; and you look to the medical journals for tactful reminders of current views and for original articles on recent work.

In this sad new world an observant eye must be kept on the trend of medical reconstruction. Do we not find that the General Practitioner Obstetrician is to surplant the Family Doctor? But, surely, human nature will be much the same, and the sick body will still look for individual care. It is still true that the patient gets the doctor he deserves.

G. M. LL.

A WANDERER SPEAKS

WHEN one day at the old "King's" in Portugal Street a contemporary H.S. said, "Sammy, I'm going to join the Navy; you'd better come along too," I little thought that that was the beginning of a roll which, in spite of the old adage, has resulted in the gathering of many mossy memories and experiences, if not of fame and fortune.

I think a policy of *carpe diem*, a little unusual perhaps, must have been mine in the Navy, for during my first commission on the China Station, in addition to learning to shoot, I wangled a long leave to Peking. I shall never forget how enormously impressed I was by the work done there by the London Medical Mission—there's another very worth-while suggestion, incidentally, for novices shivering on the brink of professional life. This was followed by an even longer leave with the avowed object of "exploring and reporting on the hot springs of Japan." What a nerve! But it led me all over the Islands before they were hopelessly westernised. Finally, by paying a bit extra, I came home via Canada, Niagara, and New York. This was followed by two years in a boys' training establishment, where one had the experiences of starting and running a pretty successful ship's magazine and of training racing cutters' crews.

During a South African commission, again, one long leave to the Victoria Falls, Kimberley, and Mafeking; another through the big-game country to Nairobi and Naivasha; and a third into German South West Africa were obtained before World War I clamped down on such delights. Whilst on this station I had a little experience of deep-sea diving and can appreciate the intense pain in the ears from too sudden compression. I also went away for a week or so in a Durban whaler and, by way of contrast, worked as a labourer picking fruit on a large farm and also in the Cape vineyards.

During World War I I was seconded for a year to the (then) R.N.A.S. and did a little flying—never solo—over Mudros and the Ægean. Around 1919 I was in a small hospital ship up the Dvina, where we were engaged in protecting the Russians from the Bolsheviks! This led, alas, to initiation into the attractions of black-marketing, and (to my shame) I learnt a bit of the trickery of the fur trade. Incidentally, the little ship was posted as "lost with all hands" on the way home across the North Sea; but this was an exaggeration. Other happy little jobs came my way, such as that of medical officer to the British Olympic teams in Antwerp in 1920. I even got a kick out of being M.O. at the Naval and Mi Tournament.

My first post-Navy venture was an ill-fated cine graphic expedition into French West Africa, cannibals, pigmy tribes, wild beasts, and wh Alas, funds failed and we never even made Timb I worked my passage home to Cardiff with a monkey, Zuzu, as my most cherished possession liquidate debts I was in a cable ship off the west of South America for three years. Apart from trip the Amazon and to the Paulo Alfonzo Falls—fun waterfalls have always attracted me—and a sp practice on a convict island, this was dull going. was almost criminal error on my part *not* to get hom the Andes and up the east coast. It led, howev the next dozen years or more in the Merchant proper, with voyages to North and South China, Japan, India, Australia, and New Zealand say nothing of many cruises round Europe, the New West Indies, and other parts.

In spite of Dr. Brett Young's scathing remar in his *Jim Redlake*, I think, that he characterises the surgeon as a slovenly, elderly man with a scurfy collar and a breath heavily charged with whisk orange-peel—there is much to be said in favour of doctoring, especially for a bachelor. I believe the much-discussed "status of the ship's surgeon" is steadily rising. But he may as well disabuse his right now of the idea that it is possible to "read board. Another fallacy is that a ship's surgeon more or less a sinecure. A modern ship is often a m machinery, and the doctor who has charge of thousand souls or more on board with three or four tious diseases, a couple of confinements, and an ap is not devoid of responsibility. The fact that he no cares of house or car or domestics and almost *night work or bad debts is on the* credit side. There undoubtedly debits, including perhaps a superfic of professional outlook. Many might not care for uniform or the discipline, or for the dictum that passenger is always right." And one *does* weary of with actual or prospective patients. But the surgeon certainly learns to exercise an infinity of tact judgment, and (among other things) to em. Incidentally, I once tried for a few days keeping watch in the stokehold in the tropics, and learnt thing at first hand about fireman's cramp.

Between voyages I used to do "locums" at hospitals—often at the same *friendly one*. The pat greeting, "Glad to see you back, doctor—you're one of us, you know," provided food for refle Anyway, I was stimulated to try for a D.P.M., and my intense astonishment, I got it.

In the last war, apart from a few months in a doing naval experimental work and a brief spell as R.A.M.O., I was mostly engaged in civil-defence But I had some useful experiences, too, as a privat Home Guard. Only fairly recently have I got into habit of taking such novel-to-a-doctor holiday cherry-picking, hopping, and agricultural labour *find in such work real recreation, especially* as I the time being no longer "doctor" or even but, more often than not, "that bleeder, Jim."

In an effort to forget and to round off things after war, I went in a newly built factory ship on an Ant whaling expedition. It was extraordinarily inter and often exciting. My panel was some 1000 men, rather fierce climatic conditions and with a huge f going night and day for five months or so. Oddly the need seemed to be for a psychiatrist rather th a physician or surgeon. There were great opport for research in comparative anatomy and oceanogr Incidentally, the *goodness or badness* of a season not affect the surgeon financially, for he alone personnel is not entitled to bonus.

Many of the delights of a fixed home and practice escaped me; but there is a great store of memories almost every day one finds that the rolling stone's ground helps not a little in the human approac patients—and others. Any road, as they say, from present peaceful backwater of a P.O. cable ship I write "no regrets"—except for the thousand and things that I have *not* done.

J. L.

itional beds are being secured for WESTMINSTER CAL medical school. The Infants Hospital, t Square, and All Saints' Hospital have already amalgamated with the Westminster, and two amalgamations are anticipated. The total r of beds for teaching is expected to rise to 700 years, and eventually to 1000. It is hoped that school, with anatomy and physiology depart- will be completed within five years; the annual may then be increased from 40 to 80 or 100. The ilum has been revised. The number of set lectures en increased, and the teaching, formerly in three has been divided into four terms a year. A three- course is now given in the new pædiatric unit. ime directors of the departments of medicine, y, and obstetrics and gynæcology have been ited to coördinate teaching. The Westminster, ts small number of students, is able to provide ant experience of midwifery, and in future students evote three months continuously to the theory practice of the subject. From September each it will reside for a fortnight in an infectious- es hospital. Proposals submitted to the university le the provision of full-time chairs of biochemistry, ine, and surgery. Wednesday afternoons have been for games; and formal instruction ceases for three in August. A health supervisory service will be ited in October; the scheme will include an annual al inspection, under the direction of a physician will be available for consultation at any time. en students, amounting to 15% of the annual will reach the school from King's College in 1948. Two courses for R.A.M.C. officers have been luring the past year.

he SCHOOL OF DENTAL SURGERY of the ROYAL DENTAL TAL of London the curriculum for the first two years es the study of dental mechanics, dental prosthetics, roperties of dental materials, general anatomy and ology, and special anatomy and physiology. The ny and physiology courses are held at King's College Strand. For the second two years students attend es and clinics on general medicine and surgery at Charing Hospital medical school, and lectures and practice in l surgery at the dental school.

Other English Schools

DURHAM UNIVERSITY up to 95 students are now ted each year. It is very difficult to absorb this er in the clinical departments, and the university l, therefore, welcome a decrease in numbers. The luctory clinical course is being reorganised in dance with the recommendations of the General cal Council. The whole-time chair of psychological cine has now been filled, but teaching for the diploma ins in abeyance until the new department is firmly lished. The teaching of anæsthetics is also under w following the appointment of a reader in anæs- s and director of the anæsthetics department in eaching hospital. The recently established Nuffield rtment of Industrial Health is embarking on its amme of laboratory and field research; in con- ion with the department of medicine it is taking in undergraduate teaching. Postgraduate teaching ublic health is being resumed, and the first e for the certificate and diploma will start in ber.

e UNIVERSITY of BIRMINGHAM * introduced last the teaching of anatomy and physiology as a single rated discipline. The scheme is flexible, and rience may dictate adjustments; but so far the riment has been entirely successful. Among the advantages claimed for this innovation are the breakdown of artificial barriers between the preclinical subjects, and the pruning of unnecessary detail. It is proposed that in future each senior student shall reside for two weeks in the city's infectious-diseases hospital. A course on tuberculosis is to be introduced in the final year. Full-time professors have been appointed in the departments of medicine, surgery, obstetrics and gynæcology, and pædiatrics and child health; and lately a full-time first assistant has been appointed to each of these departments. Chairs have also been established in medical statistics and in neurology; and further chairs are to be set up in psychiatry and in neurosurgery; with lectures in neuropathology, neuro-anatomy, and neurophysiology, the three related departments will form a school of neurological studies. The department of social medicine has got under way; and the course for the D.P.H. has been re-established.

At the UNIVERSITY OF LIVERPOOL * formal lectures during the last three years are to be concentrated into the mornings of two days each week; there is a particular need for this rearrangement because the teaching hospital is composed of four separate units, three of which are at some distance from the university. The teaching of pathology and bacteriology has been spread throughout the fourth, fifth, and part of the sixth years, thus avoiding the professional examination in pathology at a time when students should be concentrating on clinical clerking and dressing. A beginning has been made with the scheme for selecting some half-dozen of the best second M.B. candidates for an honours B.SC. in physiology; competition is keen. Scholarships covering at least the fees of the additional year are granted to the best candidates. In postgraduate teaching full-time courses have been introduced not only for the M.CH.ORTH. and for the M.RAD., but also for the CH.M. This venture aims at a combination of academic and clinical teaching; it is open to graduates of all universities, provided that they have previously covered their instruction in anatomy and physiology, and have held registrarships in surgery and/or lectureships or equivalent experience in anatomy, physiology, and pathology.

MANCHESTER UNIVERSITY * now has well over a thousand applications for the hundred or so places it can offer each year. In line with the establishment of a full-time chair of medicine in 1945, a full-time chair of surgery was established last December, and an appointment has recently been made to the new chair of child health. A pathological director has been appointed to the new centre for the study of chronic rheumatism. Postgraduate training is being developed in a number of special subjects—occupational health, child health, orthopædic surgery, cardiology, hæmatology, neurology, radiodiagnosis, radiotherapy, and ophthalmology.

At the UNIVERSITY OF LEEDS * the intake cannot be increased beyond 75 each year without further building. The undergraduate course once more extends to five years and two terms. The 1st M.B. course is closely integrated with the rest of the curriculum: the teaching in zoology is designed as an introduction to anatomy and physiology, and the standard of organic and physical chemistry studied in this course is in most other schools reached only at a later stage. Under Ministry of Labour regulations the Leeds 1st M.B. course is recognised as "medical course proper"; and the university does not generally grant exemption from it. During the course attendance at a class of medical mathematics is required of all who have not reached "principal" standard in mathematics in the higher school-certificate examination. During the first year of the 2nd M.B. course undergraduates are encouraged to attend classes of general cultural value. For the doctorate of medicine a thesis is now once more required, and usually there will also be an examination. A chair in forensic medicine has been established. For rheumatic research the appointment of a full-time director and of a research fellow has been approved. It is hoped that the recent establishment, with the help of the University Grants Committee, of scholarships enabling gifted students to interrupt their medical training in order to take an honours B.SC. degree in one of the

---

entrance requirements for the Universities of Manchester, iverpool, Leeds, Sheffield, and Birmingham are laid down in the amphlet *Qualifications for Entry upon a Degree Course*, copies of which may be obtained from the Secretary to the Board, 315, Oxford Road, Manchester, 13. War Emergency Regulations are lso in operation but will be withdrawn on Dec. 1. Any andidate satisfying those regulations before that date will be ualified to enter upon a degree course at any time. Additional aculty requirements may, however, be imposed: details can be obtained from the dean of the faculty of medicine in each

This autumn the departments of anatomy and physiology are to be reopened at CHARING CROSS HOSPITAL medical school, under the direction of professors appointed by the university. For the past 36 years students have attended King's College for preclinical teaching. Under the new arrangement they will have a better chance of appreciating the vital link between the preclinical subjects and subsequent clinical work; in the wards will be demonstrated the breakdown of some of the normal functions studied in the physiology department, and conversely clinical students will be able to return to the preclinical departments during their clerkships. The change necessitates considerable alterations and extensions to the school buildings; at the same time accommodation will be made for women students, who are now to form 20% of the annual entry. Despite setbacks, it is hoped that the work will be completed in time for the opening of the term on Oct. 13. This extension is designed to cover only the interim period until the new medical centre, with a 1000-bedded hospital and a school for 100 students, is built at Harrow. A feature of the teaching is the emphasis on outpatients' work; all the senior members of the honorary staff teach in the outpatient as well as the inpatient department; and clerks are allotted outpatient cases, which they follow through up to discharge.

ST. GEORGE'S HOSPITAL, with 103 clinical students, is one of the smaller schools. The firms are small, the number in each not exceeding 6–8. Women have been accepted for training since 1945; they have done extremely well. The principal factor limiting intake is the size of the pathology laboratory, which can accept at the most 30 students. The new midwifery department, opened during the past year, has a large enough turnover to provide all the cases needed by undergraduates. During the year a 3-month introductory course to link anatomy and physiology with clinical work has been started; this includes instruction in methods of examination, and emphasis is placed on the normal and variations in the normal. A sister-tutor lectures on some aspects of nursing.

At GUY'S HOSPITAL medical school the aim has always been to encourage students to accept responsibility as early as possible, rather than to spoon-feed with too much organised teaching; but during the war, with fewer beds, increased reliance was placed on systematic lectures and demonstrations, and to some extent this continues. The object is to make good doctors rather than good examination candidates. The policy of encouraging postgraduate appointments has been successful. It was at first thought by some that, with loss of beds from bombing, few postgraduates could be accommodated. This has not proved to be so, and frequent applications for the extension of appointments are believed to reflect the usefulness of these posts rather than uncertainty about future employment.

KING'S COLLEGE HOSPITAL medical school has always included a proportion of women in its annual entry; at the present time this proportion is about 25% of the total. With some overcrowding it would be possible to increase the number; but further building, and especially more student accommodation, such as common-rooms, is needed. The school takes students only for the clinical course. The appointment of directors of clinical and pathological studies foreshadows a closer integration between the different divisions of medicine and surgery. A special feature of the teaching at King's is the system by which members of the honorary staff hold special tutorial classes.

The LONDON HOSPITAL was damaged during the war and is now maintaining 630 beds, but by October 694 will be available; this, under existing circumstances compares favourably with the 894 beds which were maintained before the war. Nevertheless, it is hoped that priority for rebuilding damaged wards will be granted by the Ministry of Health. An annexe of 260 beds is still being maintained at Brentwood, where students attend for special classes and demonstrations, particularly in tuberculous diseases of the chest.

ST. MARY'S HOSPITAL medical school, which completely rebuilt and opened shortly before the has carried out a number of improvements to laboratories in the chemistry, physics, anatomy, physiology departments and to the medical Women students are being admitted in October, a temporary building to give increased accom tion for them will be constructed during the session. The introductory clinical course, was commenced last October to help students the transition from preclinical to clinical has been a great success, and liaison with hospitals has added to the number of beds teaching.

The MIDDLESEX HOSPITAL is still taking advant the resources for clinical teaching at the Central Mi Hospital, Willesden, as well as at the Mount Hospital, Northwood: students attend at one of these hospitals for three months, the remainder clinical instruction being received at the Hospital itself. Twelve women students have accepted for the coming session. Special con held for those intending to sit the exam for the diploma in radiology and for the F.R.C.S. Two new chairs, one in clinical and the other in clinical surgery, have been tuted this year; and readers have been app to the departments of bacteriology, anatomy, physiology, each of which is already headed professor.

The LONDON (ROYAL FREE HOSPITAL) School MEDICINE FOR WOMEN is to admit men this the first time. Accordingly, the title of the has been changed to the Royal Free Hospital of Medicine. Next year the entrance exami is to be abandoned; candidates will be selected interviewing committee. The buildings are very crowded, but repairs to the damage caused by in February, 1945, were completed by the beginn last session, and all departments are open again. hoped that an extension of the buildings on an adj site will soon be possible; this will allow of some sion in numbers. Facilities for clinical teaching been increased by the reopening of still more at the Royal Free Hospital, and by expansion annexe at the old London Fever Hospital in Liv Road.

From next October all ST. THOMAS'S HOSPITAL stu will be taught in London. The division of the into two parts, one in London and the other at Hyd has not been successful, and its continuance would difficult for both staff and students. It was de in 1937–38 that the school should be rebuilt; and hoped that priority may be granted for this pu The hospital is also to be rebuilt and may event have 1000 beds on one site. In the meantime, the is to have 500 beds open by the end of this year over 600 soon after, but some of these will be in temp accommodation. Clinical training is gradually centred round academic units of medicine, sur and midwifery and gynæcology, which will ultim take over the coördination of all teaching in departments.

The WEST LONDON HOSPITAL continues to women students who have completed their prec course. This year entrants will number about 30, is the largest intake possible under present condi The nearby Fulham L.C.C. hospital, where the the school has charge of beds, is being increasingly for clinical instruction. The university has asked school to become a member of the Postgraduate F tion with a view to training specialists in general and general surgery. This proposal, which would the abandonment of undergraduate teaching in near future, is under consideration by the govern the school. There is every prospect that students at the school, and others to whom vacancies have promised will be able to complete their training at the West London Hospital or at one of the London schools.

dmitted by competition in the preliminary examina- and the schools accept women as well as men.

QUEEN'S UNIVERSITY, BELFAST, limitation of entry be continued; and during the coming session 112 nts will be admitted. Applicants numbered over there is a carefully graded system of priority, first ity at the moment being given to ex-Service men vomen of Ulster origin. During the past year a new culum has been introduced in accordance with the ral Medical Council's report. A new full-time chair rgery has recently been filled; and a full-time chair cial and preventive medicine has been created. The al departments are to be rebuilt on the Grosvenor l site, so that they will be near the teaching hospital h is already on this site. It is hoped that at least orary buildings will have been erected within a

The NATIONAL UNIVERSITY OF IRELAND has colleges in Dublin, Cork, and Galway.

At UNIVERSITY COLLEGE, DUBLIN, a new scheme for limiting the number of students has been adopted; students will be selected by the results of the premedical examinations. Owing to increased costs, it has been necessary to raise the college fees payable by new students.

At UNIVERSITY COLLEGE, CORK, zoology has been transferred from the first year of the professional course to the premedical year.

At UNIVERSITY COLLEGE, GALWAY, students must now pass the premedical examination within two years of starting the course; and they must pass the first and second medical examinations within two years of passing the previous examination.

Degrees and Diplomas

EXAMINING BOARDS

ish, Scottish, and Irish Conjoint Boards

IE Examining Board in England of the Royal College 'hysicians of London and the Royal College of eons of England examines candidates for the ifying diplomas of M.R.C.S., L.R.C.P. Candidates fying the board's regulations in regard to the minary examination in general education are ble for admission to the premedical examination in nistry, physics, and biology, and are required to plete the professional curriculum subsequently at a gnised medical school. The emergency regulations oduced as a war measure will hold until further notice. er these, the medical course has been reduced from o 54 months, and candidates are admissible to the subject of the final examination after 30 months linical study instead of 33. The regulation permit- a candidate to enter for one part of the final after months of clinical study still holds. Some other -time concessions are still authorised in the regula- s: for example, clinical study may be undertaken ny hospital provided the dean of the candidate's ol is satisfied as to the instruction available and s the certificate of study. Other modifications will ound in the Emergency Regulations, copies of which, 1 a calendar showing the dates of examinations, may obtained, free of charge, from the secretary to the mining Board in England, the Examination Hall, en Square, London, W.C.1.

he Royal College of Physicians of Edinburgh, the al College of Surgeons of Edinburgh, and the Royal ulty of Physicians and Surgeons of Glasgow have an ngement by which, after one series of examinations, l in Edinburgh or Glasgow, or both, the student may ain the diplomas—designated by the letters L.R.C.P.E., .C.S.E., L.R.F.P.S.G.—of all three bodies. Candidates y work for the examination of the Scottish Con- it Board at any of the recognised medical schools reat Britain and Ireland. The course lasts only five rs and includes, in addition to the pre-registration mination, four professional examinations: the pre- dical examination (biology, chemistry, and physics); second examination in anatomy and embryology, siology, biochemistry, and biophysics; the third in hology and bacteriology and pharmacology; and final in medicine, surgery, midwifery, forensic dicine, and public health. Details may be had from registrar, 18, Nicolson Street, Edinburgh.

he Conjoint Board of the Royal College of Physicians Ireland and Royal College of Surgeons in Ireland epts candidates for the L.R.C.P.I. and L.M., L.R.C.S.I. l L.M. from most of the recognised medical schools at ne and abroad. Full details of the regulations can be ained from the registrar, Royal College of Surgeons Ireland, Dublin.

othecaries' Licences

The Society of Apothecaries of London grants the I.S.S.A. Lond. to candidates who pass in the primary examination (which is held quarterly) and the final examination. Final examinations are held monthly, except in September. The minimum period of study is normally five years. The four parts of the final examination may be taken together or in any order. Regulations and a schedule of the required courses of study may be obtained from the registrar, Apothecaries' Hall, Black Friars Lane, E.C.4.

The Apothecaries' Hall of Ireland grants the diploma L.A.H. Dubl. to students who have passed the three professional examinations. The diploma confers on holders the right of registration on the Medical Registers of Ireland and Great Britain. Examinations are held three times yearly, in March, June, and November. Further information may be had from the registrar, 95, Merrion Square, Dublin.

UNIVERSITY DEGREES

Bachelor of Medicine and Surgery

All the universities in the United Kingdom offer baccalaureate degrees in medicine and surgery, conferred on the results of examination.

HIGHER QUALIFICATIONS

Those who have graduated in medicine and surgery are at liberty to seek higher qualifications if they wish.

Doctor of Medicine and Master of Surgery

Graduates holding a bachelor's degrees can take the degree of Doctor of Medicine or Master of Surgery. All the universities in Great Britain and Ireland confer such degrees. The requirements vary and can be obtained from the different universities. London University offers the M.D. in general medicine, and in pathology, psychological medicine, midwifery and diseases of women, hygiene, and tropical medicine; the M.S. is obtainable in general surgery, and in dental surgery, ophthalmology, and laryngology, otology, and rhinology. At the University of Durham the degree of Doctor of Surgery (D.CH.) is offered in addition to the degree of Master of Surgery (M.S.). Liverpool offers the orthopædic degree of M.CH. ORTH.

Master in the Science of Obstetrics and Master of Midwifery

The Irish universities grant the degree M.A.O. The Society of Apothecaries of London grants the Mastery of Midwifery (M.M.S.A.) upon examination in obstetrics, pædiatrics, and public health. The examinations are held in May and November, and regulations may be obtained from the registrar, Apothecaries' Hall, Black Friars Lane, E.C.4.

MEMBERSHIP AND FELLOWSHIP

The Royal College of Physicians of London confers the Membership (M.R.C.P.), which is obtained by examination. Examinations are held four times in each year, and medical graduates and licentiates of the college over twenty-three years of age may sit for it. Details can be obtained from the secretary, Royal College of Physicians, Pall Mall East, London, S.W.1. Fellows of the college are elected annually at a general meeting of the college.

preclinical or ancillary sciences, will help to augment the supply of research-workers.

At SHEFFIELD UNIVERSITY * a revised curriculum will be introduced in October. The conditions under which exemption from the 1st M.B. examination may be granted have been extended. Five terms in the second and third years will be devoted to anatomy and physiology, followed by the 2nd M.B. examination, in these subjects, in March of the third year. This will be followed by a three-month introductory clinical course and instruction in the elements of pathology, bacteriology, and pharmacology. The subsequent period of clinical study will occupy 36 months. Students will sit the final examination (in medicine, surgery, and midwifery and gynæcology) in June of the sixth year. The first part of the third examination (in pathology, bacteriology, and pharmacology) will be held in the preceding June, and the second part (in forensic medicine, social medicine, and public health) in December. A number of full-time clinical teachers, including professors of medicine and child health, have been appointed. The departments of anatomy and physiology have been considerably extended, and the anatomy department is to take over the teaching of histology. A full-time dean of medicine has been appointed in view of the increase in administrative work. Plans have been prepared for a new medical school and a new teaching hospital.

BRISTOL UNIVERSITY, like others, has problems of accommodation. Temporary additional buildings have been erected for the departments of anatomy, physiology, and pharmacology; and the pathology department has been expanded by adaptation of an existing building. New construction for the departments of medicine and surgery is under way. These additions will enable the school to take, in moderate comfort, an entry half as great again as the pre-war number. Additions have also been made to the students' halls of residence, and the university has purchased a number of houses which are being let as flats to members of the staff. Departmental staffs are being considerably augmented. With the object of lightening the heavy burden in the part-time post of dean, the university has decided that the office shall rotate among the professors in the faculty. Responsibility for preclinical students will pass to the new post of preclinical tutor; the clinical dean will become responsible for clinical students; and administration of the faculty will pass to the university registrar. The director of postgraduate students will continue as hitherto, to deal with all postgraduate business. The new chair of child health has just been filled, and two new full-time dental appointments have been instituted —a chair in dental surgery and a lectureship in children's dentistry.

Wales

The WELSH NATIONAL SCHOOL OF MEDICINE, like other schools, is trying to increase its intake but is badly cramped for accommodation. More clinical than preclinical students can be accepted because the large municipal hospital at Llandough is in use as a supplementary centre for clinical teaching; and a scheme is on foot for enlarging this hospital. There is also a larger plan for a 1000-bedded teaching hospital in the centre of Cardiff; attached to it will be a new medical school, including departments of anatomy and physiology. Medical education in Wales has hitherto been divided between the University College of South Wales and Monmouthshire, and the Welsh National School of Medicine; every student is required to graduate in arts or science at the college before beginning his clinical studies in the School of Medicine. It is felt by some that this arrangement prevents the proper dovetailing of preclinical and clinical work, and that the growth of the clinical curriculum might be compensated to some extent by encroachment on part of the two years now entirely devoted to anatomy, physiology, and organic chemistry. It is conceded that the most promising students should be encouraged to read for an honours degree in science; but as this would involve still another year's work it should be confined to a few of the best.

Scotland

The UNIVERSITY OF ABERDEEN has established chairs in child health and in biological chemistry; these are expected to be filled during the next New building is planned for the departments of health and of child health, in which chairs have set up; and the halls of residence are to be extended take all final-year students, instead of one-third present.

SURGEONS HALL, the school of medicine of the Colleges of Edinburgh, is a teaching body only, and no professional examinations of its own; it offers for the qualifying examinations of the Scottish, E and Irish Conjoint Boards. The school is not of the university.

Each year now the UNIVERSITY OF EDIN receives about 1600 applications for 102 places in first year. A diploma in industrial health was inst last year; and courses for the new diplomas in m radiodiagnosis and medical radiotherapy were also st Under new regulations candidates for the diplo psychiatry are required to spend at least three yea preliminary training, at the end of which they an intensive course at the university.

The medical school of GLASGOW UNIVERSITY is now largest in Britain. The intake to first-year class been increased to allow for the candidates no accepted by the two extramural colleges—Anders St. Mungo's—which have amalgamated with the sity. Since the present students of these colleges be absorbed into the university classes there will very heavy pressure on the school. The university still lasts five years, but it will certainly be extended six years from October, 1948.

At the UNIVERSITY OF ST. ANDREWS emphasis is on premedical subjects, which are taught mainly introduction to scientific discipline, though not with some vocational bias. In the period of c training every effort is made to maintain the in of the student in the laboratory services of the d ments of pathology, pharmacology, and bacteriolog for example, in the systematic course on surgery study of the pathology, bacteriology, and therap of inflammation is correlated. The teaching of p health and bacteriology has for many years been simil coördinated so that together these constitute a course preventive medicine. The final clinical year is d to intensive courses in the three main divisions of final examination. During these courses undergrad are attached to and take part in the day-to-day work surgical, medical, and obstetric wards for periods of months in each. The value of this arrangement has enhanced by the appointment during the past y of whole-time lecturers responsible for ensuring these courses are arranged to best advantage and performed conscientiously.

Ireland

TRINITY COLLEGE, DUBLIN, is accepting a consid number of ex-Servicemen, including students of school who voluntarily interrupted their studies to in the British Army. The authorities insist on a general education as being the best background for medical graduate. The long-standing practice wh all medical students are required to take modified c and examinations for the degree of B.A. is still follo Some teaching in general science at school is a preliminary to admission; but all students are requ to take at Trinity College the full premedical cou chemistry, physics, botany, and zoology. For the time Trinity College is receiving an annual grant the Irish government. This will make it possible fo number of teachers to be increased and for ce departments to be developed; priority is to be gi the establishment of a department of social medic

The SCHOOLS OF SURGERY, DUBLIN, incl Carmichael and Ledwich Schools, are attached by to the Royal College of Surgeons in Ireland. St ynx, and larynx. The final examination for the .s. may be taken in otolaryngology.

sthetics

e English and Irish Conjoint Boards offer diplomas næsthetics (D.A.). Candidates must have special ience in giving anæsthetics.

l Health

plomas in child health (D.C.H.) are granted by the sh and Irish Conjoint Boards; also by the National ersity of Ireland, with a course at University ge, Dublin.

rculous Diseases

aminations for the diploma in tuberculous diseases D.) of the University of Wales have been ned.

eriology

plomas in bacteriology are granted by the univer- of London and Manchester. The London course. at the London School of Hygiene and Tropical cine, has been resumed; it begins in October and one academic year. The Manchester course is to sumed this October.

cal Pathology

e University of London offers a diploma in clinical ology (D.C.P.), for which a year's course of study is ired.

lical Medicine

e English Conjoint Board offers a diploma in ical medicine (D.PHYS.MED.). Candidates must have a registrable qualification for two years, and must had two resident appointments occupying not less a year.

opædics

verpool University offers the degree of M.CH.ORTH.; course for it lasts fifteen months.

strial Medicine

e University of Edinburgh, the Society of Apothe- s of London, and the English Conjoint Board offer omas in industrial health (D.I.H.). The course for the burgh diploma, instituted last year, lasts nine ths.

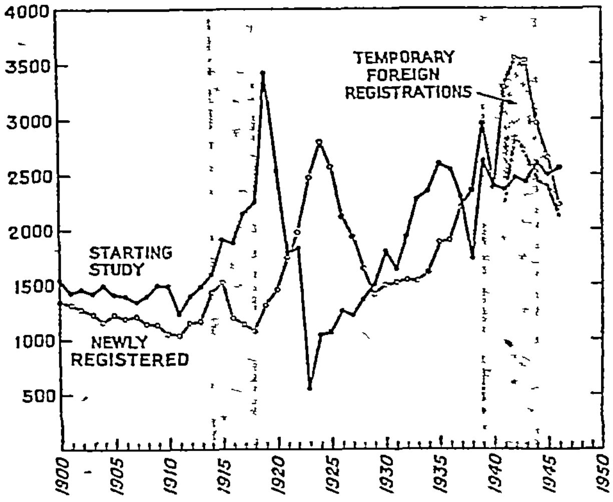
DENTAL DEGREES AND DIPLOMAS

ere are schools of dentistry at the universities of London, am, Birmingham, Liverpool, Manchester, Leeds, Sheffield, ol, St. Andrews, Belfast, and Dublin; and at the Univer- Colleges of Dublin and Cork, in the National University eland. London University offers a B.D.S., and an M.S. ntal surgery; it also prepares students for the L.D.S. of Royal College of Surgeons. This college has lately insti- d a fellowship in dental surgery (F.D.S.) Leeds grants a oma (L.D.S.), a baccalaureate degree (B.CH.D.), and master- (M.CH.D.). The University Colleges of Dublin and Cork t a B.D S. and a M.D.S., and Trinity College, Dublin, offers DENT.SC. and a M.DENT.SC. All the other universities tioned offer L.D.S., B.D.S., and M.D.S.; St. Andrews s a diploma in public dentistry (D.P.D.) in addition. nces in dentistry are granted by the Royal College of eons of Edinburgh, the Royal Faculty of Physicians and eons of Glasgow, and the Royal College of Surgeons in nd.

. . . Throughout the mammalian world the perpetuation he species has depended entirely, and in all but the latest e of human history mainly, on sexual not on parental ncts, the latter being unfolded in due course, through nological sequences, only upon the birth of the young. fact that many births, and possibly an increasing pro- ion, are planned does show, however, that parental incts are not without their effect; and the only serious blem is whether, *after contraception has severed them from sexual precursors*, they can be made effective enough to ent race suicide."—*Eugenics Review*, editorial, July, 1947,

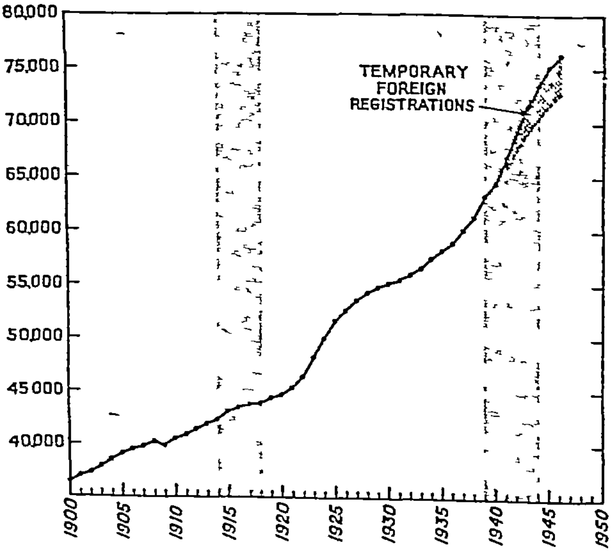
REGISTRATION

No-one is a legally qualified medical practitioner unless his name appears on the Medical Register kept by the General Council of Medical Education and Registration of the United Kingdom. The council is a standardising body, ensuring that there is a prescribed minimum of medical education and examination requirements; it is also responsible for discipline within the profession.



Numbers starting study and qualifying.*

The approximate number of second-year students admitted to medical schools in the United Kingdom and in Eire during each of the academic years 1945–46 and 1946–47 was 2600. The number of newly qualified in 1945 was 2277 and in 1946 was 2237. When temporary registration of colonial and foreign doctors ceased on Feb. 24, 1946, 825 colonial practitioners and 3551 foreign practitioners had been temporarily registered since 1940. Temporary registrations were to have been withdrawn on Dec. 31 of this year; but under the Medical Practitioners and Pharmacists Bill, now before Parliament, their duration is to be extended to allow of application for transfer to the permanent register.



Numbers on the Medical Register.

---

*The numbers shown as starting study are taken from the Medical Students' Register up to 1938; and since then from returns made by the medical schools to the General Medical Council. Both forms of registration are incomplete, but latterly returns have been received from almost all schools.

The Royal College of Surgeons of England grants a fellowship to those passing the primary and final F.R.C.S. examinations. The primary examination is open to those who hold *a qualification registrable in the British* Medical Register and to graduates in medicine and surgery of universities and medical colleges recognised by the council. Subjects of the primary examination are anatomy (including normal histology), applied physiology, and the principles of pathology. The final examination can be taken in general surgery, ophthalmology, or otolaryngology. To be admitted to the final examination in general surgery candidates must produce evidence of having been engaged in acquiring professional knowledge for not less than two years (increased to three years as from 1919) after taking a medical qualification, and of having held the requisite resident surgical posts during a part of that time. Candidates for the final examination in ophthalmology or otolaryngology must have been qualified for three years and must have held general and specialist resident posts during an aggregate period of eighteen months. The primary examination is now held in April and October; but from the beginning of 1948 it will be held in January and July. The final examination is still held in May and November. The college also grants a fellowship in dental surgery for which there is a primary examination in applied anatomy, and applied physiology and the principles of pathology, with special reference to the teeth and jaws, and a final examination in surgery, oral pathology, and bacteriology, and dental surgery. Copies of the new regulations and full particulars may be obtained from the examinations secretary, Examination Hall, Queen Square, London, W.C.1.

Medical graduates who have been registered, or eligible for registration, for at least three years may apply for examination for membership of the Royal College of Obstetricians and Gynæcologists (M.R.C.O.G.). Particulars of the regulations may be obtained from the secretary, Royal College of Obstetricians and Gynæcologists, 58, Queen Anne Street, London, W.1.

The fellowship (F.R.C.O.G.) is granted to members who are judged by the council to have advanced the science and art of obstetrics and gynæcology.

Graduates may become members of the Royal College of Physicians of Edinburgh (M.R.C.P.E.) on passing an examination, particulars of which may be obtained from the secretary, 9, Queen Street, Edinburgh, 2.

The fellows are selected from among the members *by the council of the college, and receive the designation* F.R.C.P.E.

Fellowship of the Royal College of Surgeons of Edinburgh (F.R.C.S.E.) is granted to medical graduates who pass the required examination; particulars of the regulations may be obtained from the clerk of the college, Surgeons' Hall, 18, Nicolson Street, Edinburgh.

The Royal Faculty of Physicians and Surgeons of Glasgow grants, after examination, *a fellowship registrable* by the G.M.C. as an additional qualification (F.R.F.P.S.G.). Admission is by examination and subsequent election. The candidate, who must be a licentiate of *the faculty or a graduate in medicine of a university or* medical college approved by the faculty, may be examined either in medicine or surgery. A candidate having practised a specialty for at least seven years may be examined in that special subject if the council of the faculty approves. A candidate may also submit original published work, and if this is of sufficient merit he may be excused part of the examination. Details may be had from the secretary of the Royal Faculty of Physicians and Surgeons, 242, St. Vincent Street, Glasgow, C.2.

Membership of the Royal College of Physicians of Ireland (M.R.C.P.I.) is granted on the result of an examination, the details of which may be obtained from the registrar of the college, 6, Kildare Street, Dublin.

Fellows are elected by ballot from among the members, and receive the designation F.R.C.P.I.

Graduates seeking the fellowship of the Royal College of Surgeons in Ireland (F.R.C.S.I.) must pass in two examinations, a primary in anatomy, physiology, and the principles of pathology, and a final in surgery. Further particulars may be obtained from the registrar, the Royal College of Surgeons in Ireland, Dublin

The Faculty of Radiologists offers a fellowship (F.F.R.) to medical graduates of five years' standing who have spent at least one year in general clinical work at an approved hospital, have practised radiology exclusively for three years, and have held a radiological diploma for at least two years. Candidates are required to pass an examination and submit a thesis. Candidates who hold higher medical or surgical qualifications may be exempted from the examinations in general medicine, general surgery, or pathology. Full particulars may be obtained from the warden, the Faculty of Radiologists, Lincoln's Inn Fields, London, W.C.2.

SPECIAL DEGREES AND DIPLOMAS

The regulations for the following diplomas can be obtained by applying to the examining bodies concerned.

Public Health

A diploma in public health (D.P.H.) is granted by the English and Scottish Conjoint Boards, and all the universities of the United Kingdom, except Oxford, Cambridge, and Sheffield.

Courses for the D.P.H., suspended during the war, have been resumed in most places, with curricula revised to meet the new G.M.C. requirements.

Psychological Medicine

The universities of London, Durham, Leeds, Manchester, Bristol, Edinburgh, Belfast, Ireland (National University), and the English and Irish Conjoint Boards offer diplomas in psychological medicine. (*The University of London also grants a diploma in psychology* taken chiefly by social workers.) The courses for the diploma have not all been resumed.

Radiology

The Faculty of Radiologists grants a fellowship (F.F.R.), which has already been mentioned. The University of London grants the D.M.R. Bristol and Edinburgh Universities and the English Conjoint Board offer two diplomas: one in medical radiodiagnosis (D.M.R.D.) and one in medical radiotherapy (D.M.R.T.). The Leeds University course has been extended from one to two years; the Bristol and Edinburgh courses for the D.M.R.D. last eighteen months, and for the D.M.R.T. two years. The M.RAD. of Liverpool University is granted in either radiodiagnosis or radiotherapy after a two-year course. An eighteen-month course for the D.M.R.D. is to be started at the Welsh National School of Medicine in October.

Tropical Medicine

A diploma in tropical medicine and hygiene (D.T.M. & H.) is granted by Liverpool University jointly with the Liverpool School of Tropical Medicine, by the University of Edinburgh, and by the English Conjoint Board. Courses are held at the Liverpool School of Tropical Medicine and at the London School of Hygiene and Tropical Medicine.

Gynæcology and Obstetrics

Medical graduates who are on the British Register or eligible for registration on it, may apply to the Royal College of Obstetricians and Gynæcologists for examination for the diploma in obstetrics (D.OBST.). The University of Dublin also offers a diploma (D.G.O.) for which a course is held at Trinity College; candidates spend six months as residents in one of the three Dublin maternity hospitals. The Mastery of Midwifery granted by the Society of Apothecaries of London has already been mentioned.

Ophthalmology

Three examining bodies issue diplomas in ophthalmology—the University of Oxford (granting the D.O.) and the English and Irish Conjoint Boards (granting the D.O.M.S.). The final examination for the F.R.C.S. Eng. can now be taken in ophthalmology.

Laryngology and Otology

The English Conjoint Board offers a diploma (D.L.O.) for those who have made a special study of the ear, ospital administration has been one of the main ccupations of the M.O.H. of the large county borough ounty in the last sixteen years. The National Health ice Act provides for the transfer of hospital and ialist services to new regional boards. There will be ical administrative posts in the hospital service of future, but the public-health service, as such, will be l from the burden of hospital administration and led to concentrate on preventive medicine. The ts of contact with the specialist services will be y, and full development of the social services of ital and health department should lead to closer gration in the future.

he mode of entry to the service will probably not, as he past, be through the clinical side but through stant administrative posts concerned with control of ctious diseases and organisation of clinic services. s there will be far less likelihood of medical officers have taken postgraduate qualifications in public th devoting the rest of their professional lives to ical work in a limited field. The very fact that e who undertake clinical preventive work will also ngaged in curative work will bring the administrative lical officer responsible for the organisation of clinic ices into far closer contact with his professional eagues.

he curriculum for the diploma in public health now vides a first part which is suitable for men engaged uberculosis or veneral diseases. A certificate is given those who pass the examination for part I only. course for part II provides for those who intend to e the diploma and enter the public service. Possession a D.P.H. is necessary for anyone now seeking ointment as a medical officer of health.

INDUSTRIAL MEDICAL SERVICES

HE term "industry" includes not only work in tories but also that in mines and quarries, transport lertakings, agriculture, and fisheries. The industrial dical services are at present unevenly developed, but re is growing realisation that the health of industrial rkers should be safeguarded in their work-places as ll as in their homes. The reasons for this recognition not wholly altruistic, for it is now recognised that tput depends on the health and wellbeing of the rkers. In this period of transition it is not possible forecast the final form of the industrial medical vices, but it is likely that they will be integrated with National Health Service. In any case, many doctors the future will find their life's work in industrial or cupational medicine. University chairs devoted to subject have been set up at Manchester and Durham, d readerships at Glasgow and Edinburgh. The newly ablished chairs of social medicine at Oxford and rmingham also include industrial medicine within their rms of reference, and students are likely to hear more out this subject in their undergraduate courses. Postaduate courses are held from time to time in London, rmingham, Sheffield, and Manchester. Diplomas in dustrial health have recently been instituted by e Society of Apothecaries, the Conjoint Board of e Royal Colleges of Physicians and Surgeons, and linburgh University.

Several Government departments deal with various pects of the industrial medical services. For instance e Post Office, which employs more workers than any her department, has had a medical service since 1855; d since it deals with engineering and manual workers addition to office staffs, it is partly an industrial edical service. The Ministry of Fuel and Power has a ines medical service, described below, which is responble for the health of miners; in addition, the newly rmed Coal Board is setting up its own medical service. he Ministry of Supply has a staff of medical officers hich deals mainly with the health of workers in the oyal ordnance factories. The Silicosis and Asbestos edical Board, which works under the Ministry of ational Insurance, consists of 11 whole-time and some art-time medical officers. In addition about 10 wholeme temporary doctors are employed in the South ales area to assist in dealing with outstanding claims rom miners for compensation for pneumoconiosis. The embers of the board have special experience in dust diseases, and issue compensation certificates to workers who develop silicosis or asbestosis; they also carry out pre-employment and periodical medical examinations of workers in certain industries liable to produce silicosis and asbestosis. A separate board consisting of 3 doctors was set up in Manchester in 1941 to supervise cottonworkers who develop byssinosis and to issue compensation certificates. All workmen's compensation schemes used to come under the Home Office, but they are now administered by the Ministry of National Insurance.

FACTORY DEPARTMENT

The main Government department supervising the health of industrial workers is the Factory Department of the Ministry of Labour and National Service. This department, which dates from 1833, administers the Factories Act, 1937, with its regulations on accident and sickness prevention, hours of work, amenities, first-aid and ambulance rooms, and canteens. The staff numbers about 400, of whom 16 are medical inspectors. All members of the department, whether lay or medical, take part in activities directed towards preventing illnesses and maintaining the health of the factory population. The medical inspectors are at present stationed in London, Birmingham, Liverpool, Manchester, Glasgow, and Wolverhampton; and from these centres they are able to deal with factory health and conditions in any part of the country. Under them 1750 general practitioners give part-time service as factory examining surgeons, examining all young entrants into industry, and periodically all those engaged in specified dangerous processes. They also issue certificates under the Workmen's Compensation Act for scheduled industrial diseases.

WORKS MEDICAL OFFICERS

At the end of 1945 there were 143 whole-time and 903 part-time factory officers. Compared with the 1943 figures, there were 33 fewer whole-time but 153 more part-time doctors engaged in industry. More recent figures are not available, but it can be said that the wartime expansion of factory medical services is being maintained in peace-time. At present works' doctors, except those in Government factories, are paid by private employers or firms; and the workers sometimes tend to distrust the doctors' opinions on this account. In a comprehensive medical service it should be possible to arrange that the doctor is employed by the State or by some other neutral body. Medical officers of factories who are interested in social problems have wide opportunities for their study and can also undertake the teaching of health and hygiene. They can strengthen the bonds between the factory service and the general medical and hospital services, treat accidents, reduce the chances of sepsis, follow up serious cases, and ensure that patients all return to work in the shortest time compatible with adequate treatment and reablement. Inevitably they will have to play an important rôle in the schemes for resettling disabled persons (whether from the fighting or civilian services) in industry. With their first-hand knowledge of the processes carried out and of the physical and mental capacities of the workers, they will be able to place the disabled persons in suitable jobs and keep them under observation.

RESEARCH

Apart from investigations and research into industrial diseases conducted by medical inspectors of factories, mines' medical officers, works' medical officers, and examining surgeons, much fundamental research into environmental conditions has been carried out by investigators of the Industrial Health Research Board of the Medical Research Council. Problems investigated include those of hours of work, lighting and vision, heating and ventilation, accident proneness, and sickness-absenteeism. The investigations have been mainly physiological and statistical, but clinical studies have also been made under the ægis of the Industrial Pulmonary Diseases Committee of the Medical Research Council, and include inquiries into the pneumoconiosis of coalminers and the byssinosis of cotton-workers. It became apparent that more clinical research into occupational diseases was needed, and the council in 1942 appointed a director of research in industrial medicine. In 1943 a department for research was established under the council at the London Hospital, and more recently, in conjunction

The Defence Services

Royal Naval Medical Service

Medical officers are now admitted to the Royal Navy on a short-service engagement of four years or, in the case of National Service candidates who do not wish to serve for this period, are granted temporary commissions in the Royal Naval Volunteer Reserve. Candidates must have had at least six months' experience in a house-appointment. At present no women medical officers are employed. Candidates for the Royal Naval Dental Service are entered on short-service engagements of four years only.

Opportunities are given to medical and dental officers during their temporary service or short-service engagement to apply for transfer to the permanent service. Copies of regulations and forms of application may be had from the Medical Department of the Navy, Queen Anne's Mansions, St. James's Park, London, S.W.1.

Royal Army Medical Corps

No direct applications for regular commissions in the R.A.M.C. are being invited at present. On the nomination of the Central Medical War Committee doctors are appointed to emergency commissions with the rank of lieutenant. After serving as emergency commissioned officers, medical officers have an opportunity of applying for a regular short-service commission under conditions set out in Army Council Instructions, and they may subsequently be considered for permanent Regular Army commissions. Revised conditions for the granting of these short-service commissions are to be announced shortly. Recently qualified doctors wishing to be appointed to emergency commissions should apply to the secretary of the Central Medical War Committee at B.M.A. House, Tavistock Square, London, W.C.1; or, if resident in Scotland, to the Scottish Central Medical War Committee, 7, Drumsheugh Gardens, Edinburgh, 3. Applicants should have held an appointment either as house-surgeon or house-physician for six months.

ROYAL ARMY DENTAL CORPS

As in the R.A.M.C., no direct applications for regular commissions in the Royal Army Dental Corps are being invited at present. On the nomination of the Ministry of Health dental surgeons are appointed to emergency commissions with the rank of lieutenant. Such officers may apply at once for a regular short-service commission under existing regulations, and if selected are eligible for appointment at any time to a permanent Regular Army commission. Revised conditions governing the grant of short-service commissions will be announced shortly. Immediately on qualification dental surgeons wishing to enter the Royal Army Dental Corps should notify the secretary, Ministry of Health, Whitehall, London, S.W.1.

Royal Air Force Medical Branch

A scheme to grant short-service commissions to registered medical men of British nationality who wish to serve in the R.A.F. Medical Branch, or who wish to re-enter the Service, has now been approved. By its terms doctors under 30 years of age on application (for the next few years the age will be 32) will be considered for the grant of commissions for a period of four years on the active list, followed by a period of four years on the reserve. During his service on the active list a medical officer will be considered for the grant of a permanent commission. Should he not be selected for a permanent commission he will be eligible for a gratuity of £600 on completion of four years' active-list service on the short-service commission.

The rank on entry will normally be that of flying officer, but allowance will be made for the full period of any previous service as a medical officer in the Royal Navy, the Army, the R.A.F., or the Indian Medical Service. There are also provisions under which entrants may first engage in a whole-time postgraduate appointment in a recognised hospital, or complete such an appointment if already held; in either case the period of the appointment, up to a maximum of one year, will count towards seniority in the rank of flight lieutenant. Similarly, an entrant who has previously held such a postgraduate appointment may receive an antedate of his commission equivalent to the period of the appointment, but exceeding one year. Accepted applicants will be req to serve in any part of the world and will be required pass an examination by a Service medical board assess their fitness to do so, and also their fitness as passengers. Further particulars can be obtained application to the Under-Secretary of State for (D.G.M.S.), Awdry House, Kingsway, London, W.C.1

R.A.F. DENTAL BRANCH

Those wishing to join the Dental Branch of the R should notify the secretary, Ministry of Health, Wh London, S.W.1. The granting of regular commis suspended during the war, has now been resumed, to satisfactory service in a short-service commission.

Health Services at Home

PUBLIC HEALTH

THIS year is the centenary of the appointment of first medical officer of health. In the past century improvements in environmental hygiene have achieved under the direct control of medical officers health. Gradually the standards they demanded been generally accepted and applied, and the present M.O.H. has less need to supervise this work in than his forerunner. Nevertheless much still remains be done—for instance, in improving rural water-su and urban housing. The medical officer must general control and supervision of this environm work, but its detailed execution he largely delegates sanitary inspectors, health visitors, and others. So long the general control remains with the medical officer in public health, there can be nothing but good in this.

Control of infectious diseases has always been one the main concerns of the M.O.H. The old emphasis on isolation of infected persons has now been replaced by the provision of modern hospital treatment, but there remains the active home follow-up. Bacteriologists made great advances in the identification of diff strains within certain of the pathogenic species, these new techniques, applied to epidemic control, ha given the M.O.H. an instrument of precision in much of his epidemiological work. The application of spec prophylactic measures against various of the acu infections is now a major function of health departments; and already the control of such diseases as diphtheria and enteric fever is in sight.

During the last thirty years most of the medical officers of public-health departments have been occupied in preventive clinic work. The organisation of maternity infant welfare, and school health services occupies muc of the time of the M.O.H. of a county or county borough Part III of the National Health Service Act will add responsibility for home nursing and ambulance services and will give more scope for care and aftercare. Schemes for immunisation and vaccination, health visiting, and maternity and child welfare must also be prepared. these services become obligatory for the new local heal authorities. Probably there will be a steady increase in the part played by experienced general practitioners in the clinical work, but the administration must clearly remain with the M.O.H., who is responsible for the gener organisation of preventive measures. It is probable, too that counties will devise a system of administrative through divisional subcommittees of the health com mittees, and that divisional medical officers will under take the detailed administration of the preventive services in these divisions and usually the environmental hygiene of parts of the divisions at least. This should lead to closer association between public-health medical officers and general practitioners.

The tuberculosis and venereal-disease services ar specialist clinical services which must be closely linked with epidemiological and preventive work, in which both clinician and M.O.H. are concerned. The provision of treatment is a hospital function, whether outpatient or inpatient, but more is required than this. The follow-up of contacts in both diseases is of the highest importance and in tuberculosis there is a special field of family care. This common ground should lead to closer association between M.O.H. and clinician, even though the hospital service now passes to another authority.

nistrative officers, H.M. inspectors of mines, mine ıgements, other Government departments, medical s, and other concerned.

e work of the mines medical officers is directed to -ing that the health of the mine-workers is main- d at the highest level, particularly in relation to pational factors. They are therefore concerned with vision of medical arrangements (including first-aid) ines themselves, and with ensuring that medical ment and rehabilitation are available for mine- ers following injury or illness and that these facilities sed to the best advantage. Where the provision of essary service falls short of need, it is their duty to ose improvements. They are also concerned with tigation and research into illness among miners.

ring the war years, the Ministry of Fuel and Power's cal staff was necessarily concerned with certain orary work, such as the medical aspects of recruit- , and conservation of man-power. Certain per- ent schemes, however, were put into effect, prominent ıg which is that whereby workmen who are injured e mines, where they are often not readily accessible doctor, can have morphine administered to them by ally selected certificated first-aid men employed at nines. Long-term policies were also developed, and of these are now well established, such as the ıgements for medical examination of all entrants to nning below 18 years of age and the medical iination, including X ray, of all entrants, irrespective ge, to the South Wales coalfield. Another develop- of significance is the provision at certain mines of ical-treatment centres staffed by a State-registered e who will be under the direct supervision of a or. This scheme is already in operation at a number of mines; when it is functioning fully it will provide workers with early treatment of a very high standard.

Since Jan. 1, 1947, the National Coal Board has operated the coalmines of the country in accordance with certain statutory requirements, one of which is to secure the health of the persons they employ. To implement this requirement, the Board are in the process of engaging medical staff to advise them on matters of health and to exercise medical supervision of their employees by continuing the development of the scheme initiated by the Ministry of Fuel and Power. As the work of the National Coal Board doctors develops the Ministry's Mines Medical Service will be freed to devote more of its attention to additional constructive work which has had to be left in abeyance while temporary but immediate problems were dealt with.

PRISONS AND BORSTAL INSTITUTIONS

At the larger prisons whole-time medical officers are appointed, and at the most important ones principal medical officers are assisted by one or more medical officers. Salaries are in accordance with the general Civil-Service scales, and appointments are pensionable; unfurnished quarters are provided at most prisons, at a moderate rental. Candidates with a diploma in psychological medicine are given preference, provided they have good all-round experience. Appointments are made by the Civil Service Commission, 6, Burlington Gardens, London, W.1, to whom all inquiries should be addressed.

At the smaller prisons no whole-time medical officers are employed; local practitioners are usually appointed as part-time officers. Further particulars of these appointments can be obtained from the Prison Commissioners, Horseferry House, Thorney Street, London, S.W.1.

Services Abroad

COLONIAL MEDICAL SERVICE

ACANCIES in the Colonial Medical Service occur most ı in tropical Africa and Malaya. Medical officers required, to replace normal wastage and to provide for expansion; they must be British subjects ing a medical qualification registrable in the United gdom, with at least twelve months' experience since ifying, preferably in hospital appointments. Candi- s must have been born on or after Jan. 1, 1907, in addition, special contract terms are available for up to the age of 45 or for younger candidates who ld prefer to serve in the Colonies for a term of years er than for their whole career.

edical Officers are appointed in the first instance for ral service or for health duties. There are oppor- ties for field investigation, and posts are filled from ıin the service for work in special branches of icine and surgery and in public health. Medical arch departments exist in the larger Colonies. cialist appointments are usually reserved for officers ling higher appointments who have shown out- ıding merit in a particular branch of medical practice. pecial grade of medical officers has been created in st Africa for those holding higher qualifications, to ch direct entry is made. Opportunities to gain e qualifications will be made available whenever sible, and selected candidates may be required to nd a course of instruction in tropical medicine and ıene before proceeding overseas, or else to attend h a course during their first leave period. Vacancies occur in greater numbers in future for women with erience in gynæcological and maternity work, school lic health, and child welfare.

arious government medical departments employ ut 700 European medical officers, including some 30 nen, and about 1200 locally appointed medical cers. Depending upon the territory, such diseases malaria, yaws, leprosy, sleeping sickness, plague, low fever, cholera, and other conditions associated h the tropics are encountered in addition to the usual eases experienced in any medical practice. An officer the Colonial Medical Service has special opportunities the practice of preventive medicine, as well as ortunities for teaching and research.

The medical and health services will be considerably expanded in order to fulfil the schemes for public-health development already planned. Full particulars of terms and conditions of service may be obtained from the Director of Recruitment, Colonial Office, 15, Victoria Street, London, S.W.1.

SOUTHERN RHODESIAN MEDICAL SERVICE

The government of Southern Rhodesia maintains a medical and public-health service with an establishment of 18 whole-time administrative, specialist, or public-health officers and 49 government medical officers.

Rates of pay for the whole-time officers are:

	Annual Salary
Medical director	£1900
2 assistant health officers	£1450–£50–£1600
School medical officer (man)	
Field officer	
3 radiologists	
2 directors of laboratories	
Government pathologist	
Government psychiatrist	
Medical superintendent, mental hospital	
Medical superintendent, leprosy hospital	
Assistant medical superintendent, mental hospital	£1100–£50–£1250
School medical officer (man)	£935–£33–£1100
2 school medical officers (women)	

Government medical officers are graded as follows:

2 senior government medical officers	£1450–£50–£1600
47 government medical officers	£660–£27 10s.–£990

In addition to the salary scales shown, cost-of-living allowances at the rate of 10 % of salary up to a maximum of £100 are paid at present.

Whole-time medical officers and the two senior government medical officers are not permitted private practice but are allowed consultant practice. Government medical officers, except those stationed at Salisbury or Bulawayo, are allowed private practice, the value of which varies from £100 per annum upwards, according to the station. The duties of government medical officers include supervision of the 18 government hospitals and 74 native clinics, and attendance on police, boarders in government schools, and prisoners. They also undertake medicolegal work and public-health duties. Leave may be granted at the rate of one-eighth of service, and may be taken in periods not exceeding 184 days at a time. Study leave may also be granted.

After two years' service medical officers under the age of 45 can be appointed to the fixed establishment with the Ministry of Fuel and Power, a bureau for research into pneumoconiosis among South Wales coalminers was established at Cardiff. Research into industrial-health matters is also being undertaken by the university departments mentioned above.

The Association of Industrial Medical Officers was formed some years before the war by doctors interested in industrial health, and branches have been established in various parts of the country; the *British Journal of Industrial Medicine* is sponsored by the A.I.M.O. in conjunction with the British Medical Association. Information about the association may be obtained from the secretary, c/o Standard Telephones and Cables Ltd., New Southgate, London, N.11.

LONDON COUNTY COUNCIL HOSPITALS

THE hospitals service of the London County Council provides special facilities for undergraduate instruction, and opportunities for experience for medical graduates who intend either to be general practitioners or consultants or to enter the L.C.C. Public Health and Hospital Service. At the beginning of the war the service contained 97 hospitals with beds for 71,694 patients. The 79 hospitals now in use consist of 37 general hospitals, 22 special hospitals, and 20 mental hospitals and institutions for the mentally defective.

Treatment is provided in these hospitals for all kinds of acute and chronic illnesses, including fevers, tuberculosis, and mental and nervous disorders.

HOSPITALS BRANCH

Medical superintendents of the hospitals, who are expected to be experienced hospital administrators, receive £1000 to £1800 a year in hospitals with accommodation for from 160 to 1300 patients. In addition, medical superintendents are provided with an unfurnished house or quarters with payment by the Council of local and water rates.

The other full-time medical staff are classified as:

Grade	*Annual salary (basic)*
Deputy medical superintendent, class I	£850–£50–£1000
Deputy medical superintendent, class II	£800–£30– £950
Deputy medical superintendent, class III	£725–£25– £825
Deputy medical superintendent, class IV	£650–£25– £750
Senior resident surgeon, physician, or obstetrician, and senior assistant medical officer	£650–£25– £750
Assistant medical officer, class I	£455–£25– £555
Assistant medical officer, class II	£325
Senior house officers	£260
House-physicians and house-surgeons	£155

These officers are provided with board, lodging, and laundry. Clinical assistants, who are non-resident, receive £195 a year, with meals when on duty. In addition to basic salary, the foregoing medical staff at present receive the appropriate cost-of-living addition. Vacancies in the higher grades are filled as far as possible by promotion from the existing staff.

A large number of part-time consultants and specialists are employed in the various hospitals, as well as some whole-time non-resident specialists at a salary of £1500–£100–£1800 inclusive. The number of such whole-time specialist posts has recently been greatly increased, and a new grade of assistant specialist (salary scale £1000–£50–£1400 inclusive) created. These posts are in substitution for certain existing positions of medical superintendent, deputy medical superintendent, and senior resident surgeon and physician. Whole-time specialists who undertake the administrative duties of medical superintendent, also, receive an unfurnished house or an allowance in lieu thereof of £150 a year. Whole-time specialists, or assistant specialists who act as deputy to the medical superintendent receive an allowance of £50 a year.

A central histological laboratory and seven group laboratories of the pathological service serve a number of hospitals. Attached to the group laboratories are subsidiary laboratories situated in the various hospitals. Normally a medical staff of 30 is attached to these laboratories.

TEACHING FACILITIES

Courses in fever-hospital administration for the diploma in public health, which were suspended during the war period, are now being held when required; refresher courses for medical officers released from H.M. Forces are held by arrangement with the British Postgraduate Medical Federation, University of London; other postgraduate facilities remain as they were. The Postgraduate Medical School of London is at the Council's Hammersmith Hospital.

Increased use is being made of the Council's hospitals for teaching purposes. Arrangements have been made whereby maternity students have training and experience in the maternity departments of the Council's general hospitals. The fever hospitals also provide for undergraduate instruction, and, when patients are available, for demonstrations in the diagnosis and treatment of smallpox for both undergraduate and postgraduate students. Students are resident during their course of instruction in some of the fever hospitals.

26 of the general hospitals are recognised training centres for candidates for the University of London M.D. examination; 23 of them for the final F.R.C.S. examination and the diploma in anæsthetics; and 9 for the diploma and membership of the Royal College of Obstetricians and Gynæcologists. Seven general hospitals and Queen Mary's Hospital for Children, Carshalton, are partially recognised for the diploma in child health by the Royal Colleges of Physicians and Surgeons.

MENTAL HOSPITALS SERVICE

THE public mental hospitals in England and Wales are at present the responsibility of local authorities. Apart from those hospitals administered by the London County Council, there are 65 hospitals under the control of county councils, and 26 hospitals under the control of county borough councils. The hospitals vary in size from the small borough mental hospitals with about 400 beds to the large county mental hospitals with over 2000 beds.

According to the interim revision of the Askwith memorandum published this year, assistant medical officers to mental hospitals receive a minimum commencing salary of £455, rising by annual increments of £25 to £555 yearly, with emoluments which must include board, lodging, laundry, and attendance. In addition, those medical officers who possess a diploma in psychological medicine receive a further £50 per annum. Suitable provision is made for the accommodation of married assistant medical officers. In the higher posts of deputy medical superintendent and medical superintendent no uniform scale of salaries is laid down, and these vary between the different hospitals. In addition to salary, emoluments are provided which usually consist of a house, furnished or unfurnished, fuel, and light. Permanent medical appointments are in all cases established posts within the meaning of the Asylums Officers Superannuation Act, 1909.

Posts at these hospitals offer medical officers scope for initiative and promotion. Very few new appointments were made during the war, when medical staffs were much curtailed. There are now good openings.

The mental health services of the L.C.C. are responsible for a large medical service, vacancies in which are advertised from time to time. An applicant enters the service as assistant medical officer at a salary of £575 a year, rising by annual increments of £25 to £675. Salaries are graded through the various ranks to £1600, plus a cost-of-living bonus of £90 (£72 to £82 for women), paid to superintendents of large hospitals; a superintendent is also provided with an unfurnished house on the hospital premises. Assistant medical officers may be required to live in the institution which they are serving and to pay fixed rates for board, lodging, and laundry. Officers contribute to a superannuation fund. They are required to take a diploma in psychological medicine within three years of entering the service, and the diploma carries with it a payment, in addition to salary, of £50 a year. Promotion is reasonably rapid.

MINES MEDICAL SERVICE

THE Mines Medical Service of the Ministry of Fuel and Power since its inception in 1913 has consisted of a chief mines medical officer and his deputy at headquarters, and a medical officer in each of the eight main coal-producing regions of the country. These officers have been selected primarily on account of their experience of and qualifications for mining medical work; and by virtue of their special knowledge of the environmental factors in mines they act in an advisory and consultative capacity to the Minister of Fuel and Power and his administrative officers, H.M. inspectors of mines, mine managements, other Government departments, medical bodies, and other concerned.

The work of the mines medical officers is directed to securing that the health of the mine-workers is maintained at the highest level, particularly in relation to occupational factors. They are therefore concerned with supervision of medical arrangements (including first-aid) at mines themselves, and with ensuring that medical treatment and rehabilitation are available for mine-workers following injury or illness and that these facilities are used to the best advantage. Where the provision of a necessary service falls short of need, it is their duty to propose improvements. They are also concerned with investigation and research into illness among miners.

During the war years, the Ministry of Fuel and Power's medical staff was necessarily concerned with certain temporary work, such as the medical aspects of recruitment and conservation of man-power. Certain permanent schemes, however, were put into effect, prominent among which is that whereby workmen who are injured at the mines, where they are often not readily accessible to a doctor, can have morphine administered to them by specially selected certificated first-aid men employed at the mines. Long-term policies were also developed, and some of these are now well established, such as the arrangements for medical examination of all entrants to coalmining below 18 years of age and the medical examination, including X ray, of all entrants, irrespective of age, to the South Wales coalfield. Another development of significance is the provision at certain mines of medical-treatment centres staffed by a State-registered nurse who will be under the direct supervision of a doctor. This scheme is already in operation at a number of mines; when it is functioning fully it will provide workers with early treatment of a very high standard.

Since Jan. 1, 1947, the National Coal Board ha operated the coalmines of the country in accordance with certain statutory requirements, one of which is to secure the health of the persons they employ. To implement this requirement, the Board are in the proces of engaging medical staff to advise them on matters o health and to exercise medical supervision of thei employees by continuing the development of the scheme initiated by the Ministry of Fuel and Power. As the work of the National Coal Board doctors develops the Ministry's Mines Medical Service will be freed to devote more of its attention to additional constructive work which has had to be left in abeyance while temporary but immediate problems were dealt with.

PRISONS AND BORSTAL INSTITUTIONS

At the larger prisons whole-time medical officers are appointed, and at the most important ones principal medical officers are assisted by one or more medical officers Salaries are in accordance with the general Civil-Service scales, and appointments are pensionable; unfurnished quarters are provided at most prisons, at a moderate rental. Candidates with a diploma in psychological medicine are given preference, provided they have good all-round experience. Appointments are made by the Civil Service Commission, 6, Burlington Gardens, London W.1, to whom all inquiries should be addressed.

At the smaller prisons no whole-time medical officers are employed; local practitioners are usually appointed as part-time officers. Further particulars of these appointments can be obtained from the Prison Commissioners Horseferry House, Thorney Street, London, S.W.1.

Services Abroad

COLONIAL MEDICAL SERVICE

Vacancies in the Colonial Medical Service occur most often in tropical Africa and Malaya. Medical officers are required, to replace normal wastage and to provide staff for expansion; they must be British subjects holding a medical qualification registrable in the United Kingdom, with at least twelve months' experience since qualifying, preferably in hospital appointments. Candidates must have been born on or after Jan. 1, 1907, but, in addition, special contract terms are available for men up to the age of 45 or for younger candidates who would prefer to serve in the Colonies for a term of years rather than for their whole career.

Medical Officers are appointed in the first instance for general service or for health duties. There are opportunities for field investigation, and posts are filled from within the service for work in special branches of medicine and surgery and in public health. Medical research departments exist in the larger Colonies. Specialist appointments are usually reserved for officers holding higher appointments who have shown outstanding merit in a particular branch of medical practice. A special grade of medical officers has been created in West Africa for those holding higher qualifications, to which direct entry is made. Opportunities to gain these qualifications will be made available whenever possible, and selected candidates may be required to attend a course of instruction in tropical medicine and hygiene before proceeding overseas, or else to attend such a course during their first leave period. Vacancies will occur in greater numbers in future for women with experience in gynæcological and maternity work, school public health, and child welfare.

Various government medical departments employ about 700 European medical officers, including some 30 women, and about 1200 locally appointed medical officers. Depending upon the territory, such diseases as malaria, yaws, leprosy, sleeping sickness, plague, yellow fever, cholera, and other conditions associated with the tropics are encountered in addition to the usual diseases experienced in any medical practice. An officer in the Colonial Medical Service has special opportunities for the practice of preventive medicine, as well as opportunities for teaching and research.

The medical and health services will be considerably expanded in order to fulfil the schemes for public-health development already planned. Full particulars of terms and conditions of service may be obtained from the Director of Recruitment, Colonial Office, 15, Victoria Street, London, S.W.1.

SOUTHERN RHODESIAN MEDICAL SERVICE

The government of Southern Rhodesia maintains a medical and public-health service with an establishment of 18 whole-time administrative, specialist, or public-health officers and 49 government medical officers.

Rates of pay for the whole-time officers are :-

	Annual Salary
Medical director	£1900
2 assistant health officers	£1450–£50–£1600
School medical officer (man)	
Field officer	
3 radiologists	
2 directors of laboratories	
Government pathologist	
Government psychiatrist	
Medical superintendent, mental hospital	
Medical superintendent, leprosy hospital	
Assistant medical superintendent, mental hospital	£1100–£50–£1250
School medical officer (man)	£935–£33–£1100
2 school medical officers (women)	

Government medical officers are graded as follows :

2 senior government medical officers	£1450–£50–£1600
47 government medical officers	£660–£27 10s.–£990

In addition to the salary scales shown, cost-of-living allowances at the rate of 10 % of salary up to a maximum of £100 are paid at present.

Whole-time medical officers and the two senior government medical officers are not permitted private practice but are allowed consultant practice. Government medical officers, except those stationed at Salisbury or Bulawayo, are allowed private practice, the value of which varies from £100 per annum upwards, according to the station. The duties of government medical officers include supervision of the 18 government hospitals and 74 native clinics, and attendance on police, boarders in government schools, and prisoners. They also undertake medicolegal work and public-health duties. Leave may be granted at the rate of one-eighth of service, and may be taken in periods not exceeding 184 days at a time. Study leave may also be granted.

After two years' service medical officers under the age of 45 can be appointed to the fixed establishment and contribute to a pensions' scheme. The retiring age is 60. On appointment government medical officers are usually stationed at Salisbury or Bulawayo where they are paid an allowance of £200 per annum in compensation for not being allowed to undertake private practice. They are usually required to do relieving duties at various out-stations until a permanent vacancy occurs. Appointments in Great Britain to the service are made through the High Commissioner for Southern Rhodesia, Rhodesia House, 429, Strand, London, W.C.2, who will supply further details on request.

SUDAN MEDICAL SERVICE

The Sudan Medical Service aims at providing a complete health service for the Sudanese peoples, for government officials, and for the Sudan Defence Force. The area of the Anglo-Egyptian Sudan is about a million square miles—almost one-tenth of the African continent—and the total population is probably still less than 8,000,000. In accordance with the terms of the Anglo-Egyptian Agreement of January, 1899, the country is under the joint administration of Great Britain and Egypt, and its connexion with the British Government is through the British Ambassador in Cairo and the Foreign Office.

The country is embarking on a new period of development in every sphere, and it is the policy of the government that Sudanese shall fill all government posts when they are fitted to do so by personality, ability, and training. It is therefore necessary that newly appointed British officials should be sympathetic to this policy and should be ready and willing to play their part in assisting towards its achievement.

The personnel of the Medical Service on the British side consists at present of about 40 doctors, 32 nurses, and some public-health inspectors and laboratory and X-ray technicians. On the Sudanese side there are more than 80 doctors—trained at the Kitchener School of Medicine in Khartoum—some of whom have had postgraduate experience in London, as well as public-health officers and sanitary overseers, medical assistants in charge of dispensaries, and a large number of hospital orderlies, nurses, and midwives.

The headquarters of the service are in Khartoum; and here, and in the adjacent town of Omdurman, are the central hospitals and specialist services, the Kitchener School of Medicine, the Stack Laboratories, and midwives' and nurses' training schools. The project for an entirely new hospital of over 400 beds for Khartoum has been initiated, and construction will be started as soon as circumstances permit. Outside Khartoum the country is divided into seven provinces, and in the principal town of each there is a large and well-equipped hospital. In the smaller towns there are other hospitals, each in charge of a Sudanese doctor; and there are some 400 dispensaries serving the still smaller towns and rural areas. British medical inspectors are attached to the main hospitals and may also supervise the areas in which they serve.

As there are hardly any private practitioners in the country, most medical, surgical, gynæcological, and public-health and preventive work is carried out by members of the service. There is also a varying amount of administrative work to be done: medical boards must be held, and school-children examined. Though it may be possible for work in the out-stations to be arranged so that a man who is keen either on medicine or on surgery may be able to devote himself more to the branch he prefers, all junior members of the service should be competent to undertake whatever comes their way. At present most specialist appointments are filled by selection from the more senior medical inspectors, and such promotion, which depends on the occurrence of vacancies, is rare before 12 or more years of service. All specialist appointments are held in the Khartoum-Omdurman area, and the holders may be called upon to act also as lecturers and teachers in the Kitchener School of Medicine, receiving fees in addition to their pay for their services in this capacity.

The Sudan Government having decided to suspend, for the present at least, all appointments on probation for pension, medical inspectors will now be appointed on probation for a provident-fund contract or on short-term contract. If appointment is on the former, the time-scale applicable starts at £E.840 per annum (£E = 20*s.* 6*d.*) and rises by five biennial increases to £E.1270, followed after three years at that rate by an increase to £E.1400, the grant of increases of pay being subject to satisfactory work. If appointment is on a short-term contract, the salaries will be approximately 6½% higher than the equivalent provident-fund rate. Appointment on a provident-fund contract provides (subject to an initial probationary period of two years) security for a minimum period of seven years or up to the age of 38, whichever is the later date. Subscription to the provident fund is at the rate of 7½% of salary, the official qualifying on reaching the age of 38 or completing seven years, whichever is the later date, for a government contribution equivalent to his own, accumulated at 4% compound interest. Service under short-term contract is initially for two years, but may be renewed. A cost-of-living allowance at the rate of £E.225 a year is being paid at present. Medical inspectors have prospects of promotion to posts carrying higher maxima. No income-tax is at present payable in the Sudan.

Private practice is permitted, provided that it does not interfere with official duties, but except in a few of the larger towns opportunities for private practice are few. A doctor is not allowed to charge private fees for work performed in a government hospital.

Annual leave of 80 days per annum in the United Kingdom is now being granted after the first tour of service, with free air passages from and to the Sudan. Full pay is drawn during leave periods. No free quarters are provided. Government houses can usually be obtained on payment of rent and other charges. These vary according to the station and the accommodation available, but are usually between £E.40 and £E.80 per annum.

The service provides good professional work combined with an open-air life. Work may mean travelling on inspection-tours by rail, steamer, air, car, or animal transport. The climate varies from the hot dry northern zone, through the central area which has a 3–4 months' rainy season, to the southern zone, in which conditions become increasingly tropical as the southern border of the Sudan is approached. The general level of the country rises from 1200 feet at Khartoum to 2000 feet above the sea at Nimule, on the Uganda frontier. There are good opportunities for exercise—tennis, golf, and polo being the main afternoon games. There are swimming-pools in the larger towns. In the southern zone there is plenty of shooting, and in many places very good fishing.

Applicants in the United Kingdom must be British-born and should preferably be under 35 years of age, with a good general experience. Special experience in medicine or surgery, and possession of a higher qualification will be regarded as an additional asset. An official is allowed to take his wife out to the Sudan after reaching the age of 27 or, on completing four years' service, whichever happens first, though it is not usually possible to provide family accommodation during the first tour. Candidates selected for appointment will as a general rule be required to undergo a course of instruction at either the London or the Liverpool School o Tropical Medicine before sailing. The tuition fees ar borne by the government, and a subsistence allowanc of not less than £25 a month is paid during the course

Candidates selected for appointment are given fre transport from their homes to their station in the Sudan Salary becomes payable only from the date of arriv at the Sudan frontier, but candidates are granted a allowance of half-pay up to a maximum of £20 pe month for the period of waiting in the United Kingdo for a passage until the date of sailing, and a furthe allowance up to a maximum of £E.40 to cover travellin expenses and Sudan customs dues and to compensa partly for the period of the journey during which pay not being earned.

The conditions of service given here are liable t alteration in accordance with government regulations Further particulars and information about vacanci may be obtained from Dr. H. C. Squires, C.M.G. consulting physician to the Sudan Government, 93 Harley Street, London, W.1. (Tel.: Welbeck 3423.)

Postgraduate Education

In London

The BRITISH POSTGRADUATE MEDICAL FEDERATION will a school of the University of London. For the graduate o has already started his specialist training, university artments at the Postgraduate Medical School, Ham- smith, and at institutes in association with special pitals provide organised teaching. Advanced instruc- n in general medicine, general surgery, obstetrics and ecology, and pathology is provided at the Post- duate Medical School. Institutes which are now ctioning satisfactorily are those of Laryngology and logy, Child Health, Neurology, Ophthalmology, and chiatry. Institutes of Orthopædic Surgery, Urology, eases of the Chest, Cardiology, Dermatology, and ntal Surgery are at various stages of development, l are able to provide training for limited numbers. e usual resident appointments are available at the pitals associated with these schools and institutes.

he *Postgraduate Medical School of London* (formerly the tish Postgraduate Medical School) is associated with the mmersmith Hospital, and has university departments in dicine, surgery, obstetrics and gynæcology, and pathology. tinuous teaching, based on ward-work, is supplemented lectures during three fourteen-week sessions. A course the university diploma in clinical pathology, lasting one r, begins in October. Refresher courses are held in practical esthetics. Courses are also provided for the diplomas medical radiology of the university and Conjoint Board.

The *Institute of Child Health* is in association with the spital for Sick Children, Great Ormond Street, and the tgraduate Medical School at Hammersmith Hospital, and has an arrangement with the Queen Elizabeth Hospital Children, Hackney. The institute provides tuition oughout the year in three terms of three months each.

The *Institute of Neurology* is in association with the National spital for Nervous Diseases, Queen Square. The teaching mainly by attendance on the hospital practice, and there are o terms annually. In addition, whole-time courses, each ting ten weeks, are held in the autumn and spring terms.

The *Institute of Laryngology and Otology* is in association th the Royal National Throat, Nose, and Ear Hospital at y's Inn Road and Golden Square. A comprehensive course ting twenty weeks and designed to cover the whole field of specialty is held twice a year in January and July.

The *Ophthalmic Institute* is in association with the Moor- lds group of hospitals (Royal London Ophthalmic, Royal stminster Ophthalmic, and Central London Ophthalmic spitals). In addition to teaching by means of hospital ctice, a course lasting four to five months is held twice year, starting in March and October.

Institute of Psychiatry (medical school of the Maudsley spital).—The present short course will be the last of its nd. The future training in psychiatry will be a long-term ining covering two or three years, after preliminary experi- ce elsewhere in general medicine, and it will be based on ponsible hospital duties under supervision. The ultimate n is to provide a wide clinical training in psychiatry, with ecial experience in one or more of its subdivisions.

Institute of Orthopædic Surgery (medical school of the yal National Orthopædic Hospital).—In addition to the spital practice, courses lasting six months are to be held.

Institute of Urology (combined school of St. Peter's and Paul's hospitals).—Three courses of fourteen weeks' ration are held annually.

Institute of Diseases of the Chest (medical school of the mpton Hospital).—The teaching is primarily by means of tendance on hospital practice. A whole-time programme n be arranged, but the numbers are restricted for the present r lack of accommodation. There are three terms annually.

Institute of Dermatology (medical school of St. John's ospital for Diseases of the Skin, Lisle Street, W.C.2).— inical teaching takes place in the outpatient department ce daily. A course is to be arranged for the winter.

Institute of Cardiology (medical school of the National eart Hospital, Westmoreland Street, W.1).—The aim of the stitute is to train cardiological specialists and to provide urses of instruction in cardiology for general physicians. hysicians in training as cardiologists are expected to tend whole-time for at least one year. There are three terms nually. Three intensive courses of lectures and demon- rations, each lasting a fortnight, are held in February, July, and November. In addition there are series of weekly lectures in the summer and winter for general practitioners.

In all the institutes considerable expansion is planned as soon as the necessary trained staff and accommodation are obtained. It is essential for prospective students to make their arrangements well in advance. Those sponsored by their governments or by other official bodies and selected for training in one of the specialties will receive first consideration in the allotment of vacancies. Established specialists from overseas who wish to see something of the practice of this country, and who are here for a relatively short time, are always welcome. They are regarded as visiting colleagues, and the experts in their specialties are always ready to receive them and let them accompany them in their work and teaching.

The work at the institutes is of an advanced type and is sufficiently comprehensive to enable graduates with suitable practical experience to prepare for higher degrees or diplomas. Emphasis is placed on clinical and laboratory teaching, supplemented by lectures and demonstrations. Advanced revision courses in general medicine and general surgery for graduates who have already completed their practical training and wish to sit for higher degrees and diplomas are being developed.

In addition, refresher courses for general practitioners are held at non-teaching hospitals in London and the Home Counties.

The federation has a central administrative office at 2, Gordon Square, London, W.C.1, to which inquiries should be directed. An information bureau of postgraduate medical activities in London and the other university centres is maintained.

The FELLOWSHIP OF POSTGRADUATE MEDICINE, which has a bureau at 1, Wimpole Street, London, W.1, provides general information on postgraduate work, and arranges, at various hospitals, courses of instruction which may be classed under two main headings:

1. Weekend courses, occupying the whole of a Saturday and Sunday, for general practitioners. These are given in various general and special hospitals in such subjects as general medicine and surgery, obstetrics and gynæcology, ear, nose, and throat conditions, children's diseases, and rheumatic diseases.
2. Short clinical courses for candidates for the M.R.C.P. and F.R.C.S. (final) given shortly before the examinations.

Twice a year revision courses in anæsthetics are arranged in Oxford and in London; also lecture-demonstrations for primary F.R.C.S. candidates, and occasional courses for D.C.H. candidates.

Other courses are arranged from time to time in proctology and urology. It is hoped to add to the number and variety of courses as facilities permit.

In Scotland

The EDINBURGH POSTGRADUATE BOARD FOR MEDICINE, representing the University and the Royal Colleges of Physicians and Surgeons of Edinburgh, arranges programmes of graduate studies. Two courses in internal medicine lasting eleven weeks are held, starting in April and October of each year. These classes comprise lectures, lecture-demonstrations, and clinical teaching, and are suitable for graduates wishing to specialise in medicine or who require a refresher course in the current outlook on internal medicine. Two courses in general surgery are held each year, starting in March and October. These courses are of $4^1/_2$ months' duration; they include lectures on surgical anatomy, surgical pathology, and selected surgical subjects, as well as clinical demonstrations and ward visits for sections of the class. In addition to the Edinburgh Royal Infirmary, other general and special hospitals in the city coöperate in the provision of clinical teaching facilities. General refresher courses lasting two weeks, for N.H.I. practitioners and demobilised general practitioners, are conducted according to the demand; and ten classes of this type, in addition to two short courses in obstetrics, gynæcology, and pædiatrics, have so far been held. Open postgraduate lectures on subjects of wide biological interest are arranged each term in connexion with the other organised teaching of the Board. Future plans include the further extension of hospital facilities for clinical teaching, and the provision of hostel accommodation for graduates.

The postgraduate courses are attended by large numbers of graduates from all over the world, and applications are so numerous that classes are usually filled many months in advance. Applicants wishing to attend should write, giving particulars of their medical qualifications and postgraduate experience, to the Director of Postgraduate Studies, University New Buildings, Edinburgh, 8.

GLASGOW UNIVERSITY offers the following full-time postgraduate courses: in medicine and in surgery, each lasting from Oct. 13 to Dec. 6; in obstetrics and gynæcology, from Nov. 3 to 22; and in ophthalmology, from Sept. 22 to 27. All these courses consist of clinical meetings, pathological demonstrations, and lectures. Similar courses in medicine and in surgery will commence in April, 1948. Shorter courses in ophthalmology, dermatology, and other subjects will be advertised in the medical journals from time to time. Courses are also conducted in diagnostic and therapeutic radiology.

For general practitioners refresher courses of a fortnight's duration are held throughout the year; the next such course is confined to obstetrics and pædiatrics and commences on Sept. 22. Inquiries should be addressed to the Convener, Committee on Postgraduate Medical Education, The University, Glasgow.

Some Special Courses

SURGERY

The *Royal College of Surgeons of England* has arranged a number of lectures and demonstrations to be held at the college. In surgery, two series, each of 12 lectures, will be given between Oct. 1 and 16, and between March 16 and April 2; three series in anæsthesia, each of 12 lectures, will be given between Oct. 6 and 21, April 5 and 20, and July 1 and 16. Two series in otolaryngology, of 12 lectures each, will be given between Nov. 3 and 19, and April 26 and May 11. In anatomy, applied physiology, and pathology, a series of 40 lectures will be delivered between Nov. 24 and Dec. 19, and of 72 lectures between April 5 and May 25; in ophthalmology, two series, each of 12 lectures, will be given between Dec. 29 and Jan. 13, and June 1 and 16; and in orthopædics, two series, each of 12 lectures, will be held between Jan. 14 and 29, and July 1 and 16. In March, April, and May there will be practical demonstrations in anatomy, applied physiology, and pathology. The college maintains a library, museums, and laboratories for the use of medical graduates from all parts of the world. Fellows and members enjoy these facilities by right, but they have also been made open, on suitable introduction, to other graduates of medicine, and to undergraduates. The Arris and Gale and the Hunterian lectures provide opportunities for the presentation of original work in anatomy, physiology, pathology, and surgery. The college awards several prizes for meritorious work, as well as many fellowships for those who wish to engage in practical work in the museum and laboratories or to devote some time to research.

At *St. Mark's Hospital*, City Road, London, E.C.1, surgeons wishing to specialise in proctology may attend a six-month course, and postgraduate students working for higher degrees may come for 1–4 weeks' whole-time study. Intensive courses, each lasting one week, are held, in conjunction with the Fellowship of Medicine, three or four times a year.

The *Royal College of Surgeons in Ireland* has lately held a two-month full-time course in surgery; and a further course is planned for this autumn. In October, 1947, a one-year course in anatomy, physiology, and pathology is to be instituted as a preparation for the primary fellowship examination.

PUBLIC HEALTH

Most university courses in public health have now been revived. New requirements by the G.M.C. have caused universities to revise the course for this examination, which is now taken in two parts, the first leading to a certificate in public health (C.P.H.), taken after three months' work, and the second to the diploma. The *London School of Hygiene and Tropical Medicine* offers a course beginning in October and lasting nine months, and designed primarily for those intending to seek posts as medical officers of health. All vacancies for the full course for the diploma have been filled, and there is a waiting-list, but in view of the development and subdivision of medical work in the public-health service, some places in the course for the certificate have been reserved for doctors who intend to undertake public-health work other than that of a M.O.H. The *Royal Institute of Public Health and Hygiene* also offers courses for the diploma, conforming to the new regulations: the next course begins in September.

PSYCHOLOGICAL MEDICINE

Courses for the diploma in psychological medicine are at present in abeyance at some universities. At the Maudsley Hospital medical school, now the *Institute of Psychiatry* in the British Postgraduate Medical Federation, the usual six-month course of instruction will not be given in future. Instead, there will be lectures, lecture-demonstrations, seminars, and practical work in the laboratories, which will cover the relevant aspects of psychology, anatomy, and physiology of the nervous system, psychiatry of children and adults, delinquency, pathology of nervous and mental disease, and related matters. The subjects of these lectures will be grouped so that they will meet the needs of postgraduate students at different stages of their training. At the Maudsley Hospital and associated hospitals and clinics, clinical training will be provided for a limited number of students in the various branches of psychiatry. Information can be obtained from the Dean, Institute of Psychiatry, Maudsley Hospital, Denmark Hill, London, S.E.5.

At *Edinburgh University* candidates for the diploma are now required to spend at least three years in approved hospitals, clinics, laboratories, and other institutions. At the end of this period they attend an intensive five-week course before examination. Intending candidates should enter their names with the dean of the faculty of medicine before starting special study.

At the *Tavistock Clinic* the psychotherapy of both adults and children as outpatients, based on analytical concepts, which has characterised the clinic's activities in the past, is being developed, and particular attention is being given to group psychotherapy. In addition to therapeutic work, the clinic and the associated Tavistock Institute of Human Relations are studying techniques in preventive psychiatry. These include mothers' discussion groups, selection techniques, and techniques for improving interpersonal relations in school and industry and similar psychological and sociological procedures.

Study and training are organised in three main fields: (1) individual methods, (2) social methods, and (3) child guidance. Courses, each lasting one year, are held in all three branches. The course in individual methods is designed as an introduction or supplement to specialist study in psychological medicine or clinical psychology. The course in social methods is concerned with the integrative application of psychological and other social-science techniques for the prevention, diagnosis, and treatment of community, educational, and industrial problems. Particulars are obtainable from the Training Secretary, 2, Beaumont Street, London, W.1.

The *Institute of Psycho-Analysis*, 96, Gloucester Place, London, W.1, provides training in psycho-analytic theory and technique. The course is part-time and lasts about four years. It includes a personal analysis, attendance at lectures and seminars (held in the evenings), and clinical work done under supervision. Students are required to obtain general psychiatric experience at other clinics and hospitals, since the institute does not set out to teach all aspects of psychiatry. Completion of the course to the satisfaction of the training committee qualifies the student for election as an associate member of the British Psycho-Analytic Society. In addition to this main course designed for those intending to specialise, the institute gives briefer courses from time to time on the application of the principles of psycho-analysis to medical problems. These are advertised in the medical press.

TROPICAL MEDICINE

A diploma in tropical medicine is required by those seeking appointments in the tropics. Courses are held at the *London School of Hygiene and Tropical Medicine*, the *Liverpool School of Tropical Medicine*, and *Edinburgh University*.

MEDICAL STATISTICS

In January and April, if sufficient applications are ceived, the department of medical statistics of the ondon School of Hygiene and Tropical Medicine offers a ort course, occupying two days a week for three months, the principles of medical statistics and statistical ethods. Application should be made not less than e month before the course is due to begin to the egistrar, London School of Hygiene and Tropical edicine, Keppel Street (Gower Street), London, W.C.1.

FITNESS IN INDUSTRY

At *Roffey Park Rehabilitation Centre* courses lasting e and two weeks are held for doctors, works managers, ade-union officials, and social workers. The syllabus is vided broadly under two headings: (1) maintaining ness at work, and (2) rehabilitation and resettlement. asses are modelled on the lines of the open discussion oup. Inquiries should be addressed to the Secretary, raining Department, Roffey Park, Horsham, Sussex.

THE MEDICAL WOMEN'S FEDERATION

ALL qualified medical women are eligible as members the *Medical Women's Federation*, which has active cal associations all over the country and in Northern eland, as well as a large London association and an erseas association linking up members all over the orld. The federation is non-political. It provides edical meetings for its members and publishes a arterly journal reviewing subjects of special interest women doctors. These naturally cover a wide tract social medicine, including maternity and child welfare, omen in industry, the care of children and of difficult d delinquent children, the management of nursery hools and day-nurseries, women in prisons, children in pproved schools and remand homes, the illegitimate uld, and many related subjects. Advances in obstetrics d gynæcology, and psychological studies of women and ildren are also naturally of special interest to women ctors; and recent work in these branches of medicine reviewed in the journal. From time to time the deration undertakes social studies and publishes the sults. It is also able to protect the interests of its embers by presenting arguments in any cases where ere has been discrimination against women doctors.

RITISH MEDICAL STUDENTS' ASSOCIATION

THIS association was founded in 1941, and now with he exception of three London hospitals it includes in s membership students from all the schools in England, cotland, Wales, Northern Ireland, and Eire.

The association is a purely professional body, with the le object of providing machinery at the national level promote the interests of medical students. It provides method of communication between medical students on he one hand and, for example, British and foreign udents of other faculties, the British Medical Association, d Government departments on the other.

The association has representatives expressing the tudents' point of view as members of many committees. t publishes its own journal; and it has issued a catalogue f medical films.

But perhaps the most valuable aspect of its work is o be found in the clinical conferences which it has made ossible. Three have already been held this year, at heffield, Edinburgh, and Leeds; and have given students n opportunity to meet other students, to see other ospitals, and to hear other teachers.

Expenditure last year was in excess of income; and unless he income can be increased it will be necessary to restrict ctivities. The rate of subscription from student members as been increased, but it is estimated that it will be mpossible to raise the whole of the sum needed in this way.

At the last annual general meeting it was decided to reate a new category of membership for qualified men, ho would be invited to make a donation to the association and who would receive a copy of the journal.

Any readers who feel that the work is of value are therere asked to encourage the association by becoming ssociate members. The president is Mr. Denis R. Cook, nd the office is at B.M.A. House, Tavistock Square, London, W.C.1.

In England Now

A Running Commentary by Peripatetic Correspondents

As a student I was wise enough never to lose touch with my general interests. Mark you, not every examiner shared my balanced view; some had a narrow partisan attitude to their subjects—an attitude that I and the Goodenough Committee deplore—so there were occasional misunderstandings. But I never regret my ten years as a student. In my time I picked up several useful tips, which I'll pass on for what they're worth. First of all, there should be no compunction about getting a friend to sign you up for lectures; any professor who counts an hour listening to him as an hour's study is just asking for it. Never go to afternoon lectures; if you've had a decent lunch you'll sleep, and if you haven't you'll be in no trim to listen. Just a word of warning here: always get to know by sight the man who's giving the lectures. Towards the end of the summer term of my ninth year I foolishly decided to look in at a forensic-medicine lecture; I stopped a white-coated lab. assistant to ask the way, which he told me—very civilly, I must say. I sat down in the front row (there's another useful hint —one attendance with an earnest look in the front row is worth three further back) and I waited. Then the lab. man, who, it seemed, was the professor, came in and started lecturing; so all that hour I looked kind of naturally earnest. But it was O.K.; I'd read up the right three chapters in the great man's book, and when the exam. came he raised no objection to my passing on to the final year. To the finals candidate I would say this: when you're given a case to take, get to know the patient; go right up to him and say in an easy, friendly way: "Now, old chap, the first thing I want you to tell me is your diagnosis." Very often he does, and then you can do the rest by induction. As to the written exam.— always be careful about your speling; I never had any trouble with mine, but I knew lots of poor blighters that did. Then, examiners invariably appreciate the capacity of a potential medical graduate to construct his sentences with a facile lucidity reflecting the optimum which can be made available from his educational facilities. Finally, examiners like a straight answer; if you don't know, say so and retire; it's no use throwing the ball back at them, as I once did: "well, what do *you* think, sir?" I was given six months to look up the answer for myself.

I hope these few hints will help; and I guarantee that anyone acting on them will have no more trouble than I did.

* * *

I'm not going to write about tattoos. I might just as well start to cram all about hearts into one peripatetic column. The subject merits nothing less than an entire special number of THE LANCET, with articles on *The Histopathology of Tattooing*, *The Psychology of the Tattooed*, *Tattoos and Social Medicine*, and so forth. I merely want to submit an interesting case—more interesting, I think, than the not uncommon row of blue dots across the root of the neck with "Cut Along The Dotted Line" above them: certainly more so than the quite frequent "I Love Mary" altered to an indelible declaration of affection for Katie. This tattoo was a hunt in full cry. The scene began at the umbilicus with a line of pink-coated horsemen galloping towards the right shoulder—all executed with a skilful impression of the dash and vigour of the chase. The meet continued on to the back, the hounds having got ahead as far as the spine of the scapula. The pack filled the remaining space as far as the buttocks, where the fox's brush could be seen disappearing into the anus. The tableau was labelled, sure enough, "Gone to Earth."

* * *

A wet Sunday afternoon is one of Nature's treats for hard-working doctors, and it's worth waiting for. It's strange, though perhaps natural, that few seem to dare disturb their doctor during those sacred sabbath hours twixt dinner and tea. Maybe all save the nearly moribund are replete and drowsy after their weekly roast or its post-war equivalent if such exists. Maybe they feel that a doctor is out of place on a Sunday: he disturbs the peace and would certainly upset the digestion. Whatever the cause, apart from fractures, fits, and sudden death, Sunday afternoon is comparatively calm.

And a wet one is full of possibilities. There are half a dozen birthday letters still to answer. The lino in the surgery needs nailing down. My winter coat must be altered. The dog should have his annual bath, and there ought to be time for a few more chapters of *War and Peace*. But here comes the rub. As all the world knows, two to five on a weekday is three hours; but on a wet Sunday it seems more like three minutes; and with the best will in the world even a doctor can't do more than sink into a chair, open the *Observer*, and listen to the start of the symphony concert in 180 seconds.

* * *

More Hints for Prospective Brides.—Very soon after her introduction to the practice the young wife will have to cope with Other Doctors' Wives and with Social Life. The first essential step is to write down Who's Who. The Upper Crust differ in each practice. Take the local paper and the parish mag. The people you natter to in the High Street and entertain to tea must be given a talking point. They like to be able to say something "safe" about you. Let it be known that you etch beautifully, write for *Comic Cuts*, do gouache on stretched linen (that will fetch 'em), make lovely lardy cakes, collect foreign stamps, play the bagpipes (when on holiday), have a new recipe for leek soup, sometimes have second sight, &c. &c.

Let the Other Wives know enough about your husband that is safe for them to pass on to their husbands the moment they get home, but never *talk* about him. Suggest by innuendo that his batman would have died for him and that other women find him dull (this is far from true of course).

When they come to tea (separately, always) have your husband ring you up at least four times from a call box and on one of these calls chatter away loudly in Afrikaans, Dutch, or Celtic and then return to the tea-cups sighing. This goes down well in a big-city practice. In the country you need only replace the receiver and say: "Lady Argle-Bargle in trouble again." An air of bored efficiency should be cultivated. The subject must be changed rapidly. Soon after this your husband must come in briskly, gulp a cup of tea and go, after a display of exquisite manners that would put any other husband to shame. This should not last more than two minutes, he couldn't stand it any longer anyway.

"... Lady Argle-Bargle in trouble again ..."

Then you will listen to the Other Wife's troubles (she will have a sackful, if I know her) with a wide-eyed innocence of the "Gosh! I have a lot to learn" variety.

If you are in a big-city practice a really good line is to know at least one member of the Savage Club and to have dined there often enough to be able to mention a well-known name. Or, truth can be served if one of the panel men is, say, an electrician at the Colossal Theatre. When dressing his whitlow you are sure to hear some endearing story of a favourite star. Nowadays I suppose the Stock Exchange is rather a dead letter, but when I was a girl . . . my dear, they can be worth *millions*. . . . When you've got on a bit, hyphenate the surname and pretend your husband had an Aztec grandfather. It'll fetch 'em faster than a membership and fellowship.

In the country you will find that Doctors' Wives are either well dressed or absolutely unspeakable. Decide at the outset to which class you will belong. It costs money at first but its worth it. Cultivate a taste for and knowledge of country life and all that appertains thereto—dogs, horses, saddle-back churches, elderberry wine, and antique furniture, not to mention signs and portents of the weather, the local dialect and superstitions. Remain aloof from all things political and remember that the cottager's pain is every bit as bad as the Squire's.

If you happen to be the wife of the assistant with a view (acting assistant's unpaid assistant), you will find the view often obscure and dim. It is usually a question of whose carefully prepared lunch is to spoil. The principal's wife will ring up distracted, of course, saying she can't find her Old Man anywhere and there's been an accident . . . &c. You hear the Old Man's racking cough in the middle distance, but if you are unfortunate enough to know on which side your bread is buttered you must say: "My dear, of course, right away.". If you are a hard-headed little woman (as I know you are, otherwise you wouldn't be where you are now), you just apply my method How to Deal with an Unwanted Telephone Call (see previous notes).

Of all the Other Doctors' Wives the most pleasant are Specialists' Spouses. I'm never quite sure why this is. You will count them among your real pals. On the rare occasions that they visit you, pâté de fois gras is not enough. Get up early and toss off those well-tried recipes of yours—Chinese Cake, Hungarian Bread, or Bear Biscuits. If I know these spouses they will enjoy it, and (what is really pleasant) they will say so.

* * *

If you can stand and see your patients running
In headlong scurry to the other man,
And not ascribe to evil low-down cunning
His gifts of healing far beyond your span:
If you can watch his income upward rocket
While yours is small, as all the world can see;
If you can thrive, though sadly out of pocket,
On tending back-street paupers free of fee.

If you can lend an ear to old folks stealing
Your precious time with tales of aches and pains;
If you can let each patient have the feeling
He's found in you warm heart as well as brains:
If you can say a prayer when patients need
Some ghostly comfort as they near Death's shores;
If you can tell them of some golden creed,
And gently let them feel it's also yours.

If you can tell the truth in spite of fears
That telling it will earn your patients' curses;
If you can shoulder blame, ignore the jeers,
And not make scapegoats of your loyal nurses:
If you can lie, when lying makes for healing,
And so-called truth would cloud your patient's sight;
If you can ease his going by concealing
The gruesome phantoms of the coming night.

If you can worship science as a virtue,
And keep its standards lofty, without fail;
Yet somewhere hide (for fear that it may hurt you)
A mystic's sense of things beyond the veil:
If, lastly, you will make confession
Of all the blinking flaws which make you feel
Unworthy of a great profession;
Then sure enough, my son, you'll learn to heal.

* * *

I escorted the M.D. candidate behind the screen and directed him to examine the patient's testicles. All sorts of lesions were discovered that were not present. I had hoped for the simple observation that the right was the lower, an abnormality which would have sent him looking for all the other features of complete transposition of viscera. There was even an appendicectomy scar in the left iliac region. . . .

* * *

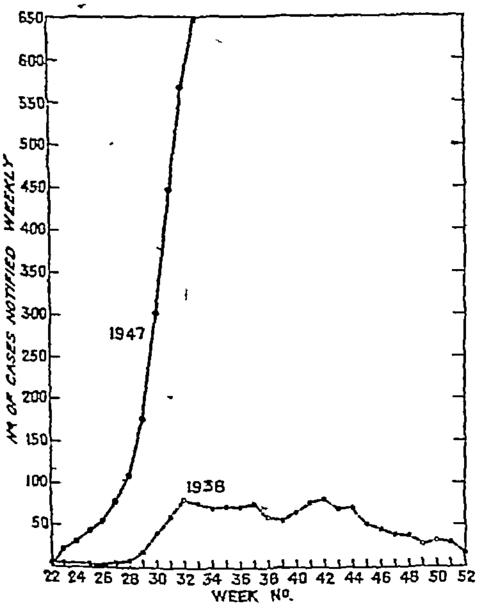
More about Emigration.—"When shall we realise the fact that the great thing needful to the prosperity of England is, not almshouses, and hospitals, and private charities, but the establishment, advocated by Mr. Carlyle, of a regular and efficient emigration! The crassest ignorance only prevents the listless pauper, the frozen-out mechanic, and the wretched agricultural labourer from quitting a scene of misery, and from finding scattered over Earth's surface spots where the memory of privations endured in the hole which he calls his home would make his exile a paradise."

Social security 1947? No, Sir Richard Burton 1863.

Public Health

Poliomyelitis and Polioencephalitis

E number of cases of poliomyelitis notified in and and Wales during the week ended Aug. 16 646. This is an increase of about 14% on the e for the previous week (568) which suggests that steeply rising curve of incidence is beginning to n out. Figures for some of the most affected ty areas are not notably different from those of previous week (given in parentheses)—e.g., London



(84), Lancs 71 (71), Durham 39 (36), Middlesex 32 (35); stantially increased notifications were reported from East Riding of Yorkshire 18 (5), Surrey 39 (24), and arwick 37 (23); there was a continued decline in the ekly figure from West Riding of Yorkshire 44 (57).

Notifications of polioencephalitis were lower than in previous week 45 (56). The distribution of notified es of this condition does not appear to be closely lated to that of the notified cases of poliomyelitis. out half the 45 cases of polioencephalitis notified in e week ended Aug. 16 occurred in areas mentioned ove by reason of their having a heavy or rising incidence poliomyelitis.

Beds for Poliomyelitis

The Queen Elizabeth Hospital for Children, Hackney oad, London, E.2 (Tel.: Bishopsgate 4633) has set side, equipped and staffed, a ward of 15 beds for the eatment of anterior poliomyelitis.

Infectious Disease in England and Wales

WEEK ENDED AUG. 16

Notifications.—Smallpox, 0; scarlet fever, 614; hooping-cough, 1870; diphtheria, 145; paratyphoid, ; typhoid, 8; measles (excluding rubella), 4468; eumonia (primary or influenzal), 253; cerebrospinal ver, 60; poliomyelitis, 646; polioencephalitis, 45; ephalitis lethargica, 4; dysentery, 66; puerperal rexia, 127; ophthalmia neonatorum, 65; relapsing ver, 0. No case of cholera, plague, or typhus was tified during the week.

Deaths.—In 126 great towns there were no deaths from eric fever, scarlet fever, or diphtheria, 2 (0) from easles, 5 (0) from whooping-cough, 66 (3) from diarrhœa d enteritis under two years, and 3 (0) from influenza. he figures in parentheses are those for London itself.

The number of stillbirths notified during the week as 253 (corresponding to a rate of 28 per thousand tal births), including 29 in London.

Notes and News

THE POLIOMYELITIS FILM

As we mentioned last week, a film has been made at the request of the Ministry of Health to help general practitioners in the early diagnosis of acute anterior poliomyelitis during the present epidemic. This film, which was made with commendable speed and has now been released, is not so much a balanced study of its subject as a "newsreel" intended to supplement the advice and information which the G.P. can get from his textbooks and journals. It opens with a graphic demonstration of the recent age-incidence of cases in London hospitals. After brief mention of the usual presenting symptoms (headache, fever, vomiting) it goes on to portray the common early signs: cranial-nerve palsies are beautifully illustrated, as also are the methods of eliciting spasm of the muscles of neck, back, and limbs; a word is spared, too, for early changes in tendon reflexes. Then comes a demonstration of lumbar-puncture technique, followed by brief observations on methods of disposal of fæces, precautions by the attendant, isolation of doubtful cases, and methods of spread; finally practitioners are adjured to notify cases, and when in doubt to consult the M.O.H.

Though the film is intended for the general practitioner there are no shots calculated to help him specifically in his encounter with the disease in the home—apart from one showing a housewife protecting her food from flies, and another portraying a doubtful case comfortably isolated in a garden. The practitioner would welcome some suggestion of the time-sequence, which would lend itself to visual presentation. Perhaps, too, he would like an explanation of how the attendants' precautionary steps, illustrated in the film by masked and gowned nurses and doctors, are to be applied in the home; and especially he wants to know what advice to give the families of established or unproven cases. As a rule he will not be undertaking lumbar puncture. If the diagnosis is in doubt (and it is on this score that the film advises the procedure) he is likely to refer the patient to hospital. Always, except occasionally deep in the country, lumbar puncture should be undertaken in hospital, where the risk of infection can be minimised; this is made clear in the spoken commentary which accompanies the film.

UNIVERSITY COURSE ON MEDICAL ILLUSTRATION

THE University of Edinburgh announces a three-year course in medical illustration, to begin in October, 1948. The course, which will be particularly suited to those considering this work as a profession, will include training in half-tone and line work, and in anatomy. Candidates, who must be aged at least 18, are required to have had a good secondary education and must have a fair knowledge of general art. Applications should be submitted to the dean of the faculty of medicine.

University of Cambridge

On Aug. 2 the following degrees were conferred:

M.D.—J. R. Bignall, G. A. Emmerson, E. M. Griffin, W. P. U. Jackson, T. W. Letchworth, R. G. Mathers, M. G. P. Stoker.

M.B., B.Chir.—W. E. C. Astle, *W. H. Barker, S. B. Bennett, M. A. J. Browne, *J. H. S. Buchanan, *J. D. Burton, *H. W. Cornford, *A. F. Crick, *M. de B. Daly, *A. B. Douglas, *M. C. Edmond, *G. R. Faber, A. W. Ferguson, N. B. Finter, *D. K. Ford, *W. D. Foster, *A. G. Freeman, J. H. Garson, K. O. George, *R. V. Gibson, J. G. Goodhart, C. L. Grandage, Michael Harington, J. G. Harrison, *R. E. * By proxy.

Dr. R. M. Fry has been appointed university director, and Dr. Joan Boissard university assistant director, of the Public Health Laboratory Service at Cambridge.

Regional Board Appointments

The *Manchester Regional Hospital Board* has appointed Dr. F. N. Marshall (a senior M.O., Ministry of Health) as senior administrative medical officer, and Mr. J. Gibbon (deputy clerk of the Lancashire Mental Hospitals Board) as secretary.

Queen's University of Belfast

On July 9 the following degrees were conferred:

M.D.—Thomas Freeman (with high commendation); R. D. G. Creery, *G. W. Csonka, F. G. C. Walker (with commendation); J. H. Adams, J. L. Blair, C. F. Campbell, J. S. Elwood, P. A. H. M. Foster, J. G. Gibson, E. H. Gordon, Wilson Johnston, R. J. Kernohan, Alice I. M. Leach, A. R. Lyons, W. J. McLeod, R. P. Maybin, *R. S. Murray, A. S. Ramsey, *B. E. Swain, N. H. Wass, R. J. Wright.

M.B., B.Ch., B.A.O.—C. A. G. Armstrong, Joan G. H. Bennett, H. C. Boyd, J. S. Brown, J. A. Byrne, Pauline M. Charlton, J. G. Clearkin, R. T. Cooke, John Erwin, Joseph Fulton, R. S. Gibson, F. S. Grebbell, Mary Gunning, Mary E. C. Henry, George Hughes, G. J. G. Irvine, Anne W. Kilpatrick, W. G. Liggett, T. E. C. Linton, H. M. McAdoo, Irene S. McCaughey, E. G. McClean, R. L. McCorry, Charles McDowell, D. J. McSparran, J. D. Morrow, P. N. Newsam, G. S. Parkes, Austin Reid, Kathleen J. Reid, P. N. Ronaldson, James Shanks, R. L. Turner, John Weatherup, Elizabeth M. Wells.

* In absentia.

University of Manchester

Mr. J. H. Kellgren has been appointed clinical director of the new research centre for chronic rheumatism, to which the Nuffield Foundation gave a grant of £100,000 (see *Lancet*, 1946, ii, 609).

Mr. Kellgren, who is 36 years of age, took his M.B. Lond. from University College Hospital in 1934, his M.R.C.P. in 1935, and his F.R.C.S. the following year. After serving for a time as chief assistant in the electrotherapy department of St. Thomas's Hospital, he returned to U.C.H. as a research-worker under Sir Thomas Lewis in the department of clinical research, and later he was appointed assistant in the surgical unit. During the war he was an E.M.S. surgeon at Leavesden Hospital and later served in the R.A.M.C. as a surgical and orthopædic specialist. On demobilisation he was appointed to the scientific staff of the Medical Research Council, and he is at present working at Oxford upon the problem of pain in rheumatic disease. His published work includes a number of papers on the localisation of deep pain and on the clinical applications of this work in diseases such as sciatica and fibrositis.

Mr. A. Morgan Jones has been appointed lecturer in cardiology and deputy director of the department, Mr. John Loewenthal lecturer in surgery, Dr. Alan Stanworth lecturer in ophthalmology, Mr. N. A. J. Young lecturer in diseases of the ear, nose, and throat, and Dr. G. S. Graveson lecturer in medical neurology.

Royal College of Surgeons of England

The honorary fellowship of the college has been conferred on Dr. Victor Veau (Paris) and on Prof. Robert Danis (Brussels). Diplomas will be presented to Dr. Leopold Mayer of Brussels, the president of the International Society of Surgery, who was awarded the honorary fellowship in December last, and to these two newly elected fellows during the forthcoming congress of the International Society of Surgery.

During September the following lectures will be delivered at the college, Lincoln's Inn Fields, London, W.C.2: Dr. Arthur W. Allen (president elect of the American College of Surgeons), Duodenal Ulcer—a comparative survey of two groups of patients, one treated by subtotal gastric resection and the other by vagus nerve interruption (Moynihan lecture, Sept. 22); Dr. Frank H. Lahey (Boston), Hyperthyroidism (Cecil Joll lecture, Sept. 23); Prof. William E. Gallie (Toronto), Recurring Dislocation of the Shoulder (Moynihan lecture, Sept. 24); Prof. Evarts Graham (Washington), Bronchiogenic Carcinoma (Lister oration, Sept. 25); Mr. Hassan Ibrahim, Bilharziasis and Bilharzial Cancer of the Bladder (Hunterian lecture, Sept. 29); Mr. Harold Wookey (Toronto), Surgical Treatment of Malignant Disease of the Pharynx and Œsophagus (Hunterian lecture, Sept. 30). The lectures, which will all be held at 5 P.M., are open to doctors, dentists, and advanced students.

Infantile Paralysis Fellowship

The National Foundation for Infantile Paralysis of America have sent the English fellowship a copy of a standard-size sound film, on the treatment of infantile paralysis, entitled New Horizons. The film is at the disposal of the medical profession, free of charge, on application to the secretary of the fellowship, 37, Tavistock Place, London, W.C.1.

Remuneration of Consultants and Specialists

The committee which under the chairmanship of Sir Will Spens is considering the range of remuneration of doctors engaged in consultant or specialist practice in any publicly organised hospital and specialist service is inviting evidence from the organisations directly interested. It will, however, be prepared to receive evidence from interested bodies or persons other than those specially invited. Memoranda should be sent to the joint secretaries of the committee, Ministry of Health, Whitehall, London, S.W.1, before the end of September.

Army Medical Exhibition

This exhibition at Stanley Park, Blackpool, which will remain open, Saturdays and Sundays included, until Sept. 6, includes demonstrations of the evacuation of casualties, water purification, and preventive medicine in the field. A small historical section contains Florence Nightingale's coach and famous lamp. The proceeds will go to the R.A.M.C. War Memorial Fund which has been formed to help the families of the officers and men of the corps who were killed or disabled in the war.

REGISTER OF CHIROPODISTS.—The sixth edition of this register has now been published by the Board of Registration of Medical Auxiliaries. Copies may be had free of charge from the Registrar, Tavistock House North, Tavistock Square, London, W.C.1.

CORRIGENDUM.—In the list of references following Dr. J. D. Paulett's paper on Low Back Pain (Aug. 23, p. 272) the fourth item should have read: Ellman, P., Savage, O. A., Wittkower, E., Rodger, T. F. (1942) *Ann. rheum. Dis.* 3, 56.

Appointments

AIDIN, A. R., M.D. Dubl., D.T.M., D.C.P.: morbid anatomist, public-health department, Bristol.

DEVAS, M. B., M.B. Camb.: senior surgical officer for orthopædic work, Oldchurch County Hospital, Romford, Essex.

LACEY, J. W., M.D. Camb., M.R.C.P.: pathologist, St. John's Hospital, Chelmsford.

LOCKET, SIDNEY, M.B. Lond., M.R.C.P.: specialist medical officer (physician), Oldchurch County Hospital, Romford, Essex.

MACQUEEN, I. A. G., M.B. Edin., D.P.H.: M.O., Department of Health for Scotland.

PATERSON, J. T., M.B. Edin.: tuberculosis officer, Barking and Dagenham, Essex.

PHILLIPS, J. J., M.B. Leeds: M.O., Nigeria, Colonial Service.

SMITH, JOHN, O.B.E., M.B. Camb., M.B. Glasg.: M.O., Department of Health for Scotland.

TAYLOR, H. B., M.B. Edin.: district M.O., Bahamas, Colonial Service.

Births, Marriages, and Deaths

BIRTHS

DEMETRIUS.—On Aug. 22, at Reading, the wife of Dr. L. F. Demetrius—a son.

FATTI.—On Aug. 11, the wife of Mr. L. Fatti, F.R.C.S.—a son.

INGRAM.—On Aug. 22, at Thames Ditton, the wife of Dr. Frank L Ingram—a daughter.

JACK.—On Aug. 20, the wife of Dr. Ronald Jack—a son.

JOHNSON.—On Aug. 18, at Romsey, the wife of Dr. Peter Johnson—a daughter.

LOWN.—On Aug. 18, at Ewell, the wife of Dr. J. F. Lown—a son.

MYERS.—On Aug. 21, at Cambridge, the wife of Dr. Geoffrey Myers—a daughter.

NORTH.—On Aug. 17, at Weybridge, the wife of Dr. John North—a son.

O'HIGGINS.—On July 22, at San Sebastian, the wife of Dr. P O'Higgins—a daughter.

PINKERTON.—On Aug. 16, in Berlin, the wife of Captain J. R. H Pinkerton, R.A.M.C.—a daughter.

POND.—On Aug. 17, in London, the wife of Dr. Desmond Pond—twin daughters.

POOLE.—On Aug. 19, at Teddington, the wife of Dr. D. S. Poole—a son.

SHARPLEY.—On Aug. 15, at Oxford, the wife of Dr. John Sharpley—a son.

SHEPHERD.—On Aug. 18, at Oxford, the wife of Mr. J. A. Shepherd F.R.C.S.E.—a son.

STEEN.—On Aug. 20, in London, the wife of Dr. Patrick Steen—a son.

TOLHURST.—On Aug. 20, at Bournemouth, the wife of Dr. D. A Tolhurst—a son.

WASS.—On Aug. 14, in London, the wife of Mr. S. H. Wass, F.R.C.S—a son.

MARRIAGES

FRYER—MCCONNELL.—On Aug. 16, at Uxbridge, Graham Joh Firth Fryer, M.R.C.S., to Catherine Hunter McConnell, Q.A.I.M.N.S./R.

GARVIE—WARDLAW.—On Aug. 23, at Sunningdale, James Macken Garvie, B.M., to Kathleen Hope Wardlaw.

HOTSTON—CARR.—On Aug. 23, at Southport, Richard D. Hotston M.R.C.P., to Mary Carr.

MARX—MOUNSEY.—On Aug. 20, at Bromsgrove, Lothar Marx M.B., to Barbara Ann Mounsey.

MAYER—LESSER.—On Aug. 21, in London, John Henry Mayer F.R.C.S., to Sheila Joan Lesser.

WILSON—AINSWORTH.—On July 28, at Bury, Lancs, Willi Weatherston Wilson, M.B., to Ruth Audrey Ainsworth, M

DEATHS

COOPER.—On Aug. 17, at Brisbane, Lilian Violet Cooper, M.D. Du aged 80.

MCMILLAN.—On Aug. 20, Arnold McMillan, L.R.C.P.E.

MURDOCH.—On Aug. 22, at Croydon, John Murdoch, M.D. Dubl.

COALMINERS

J. N. MORRIS
M.A. Glasg., M.R.C.P., D.P.H.

> "The present crisis underlines the basic importance of coal—our national existence becomes quite impossible if we cannot produce enough coal: the whole industrial programme depends upon the miners."

THE anxiety expressed in the Economic Survey for 1947[7] reflects a new situation in our society. In the inter-war years there was a reservoir of 150,000–200,000 unemployed miners—now there are not enough. Output per man, moreover, is lower and attendance less regular than it has been. The coal problem today is thus, in large part, the problem of the miners. This paper deals with some aspects of the problem: first, in terms of economics, industrial relations, and occupational hazards; and secondly, by describing the responses which followed from these and combined with them to make up the recent history of mining people. Present difficulties are considered in the light of this history and in the context of a society with full employment; and some contributions which medicine might make are indicated.

The Inter-war Years

How British industry was brought almost to a standstill for lack of coal can only be understood by reference to the past. Fortunately there is little advantage in tracing events beyond the slump of 1931 and the strikes of 1926 and 1921—events within the experience of perhaps half the men now working in the mines. During those years the industry was contracting.[48] It was faced by a steep fall in demand from abroad, and the exporting districts—South Wales, Durham, and Scotland—suffered severe unemployment. Meanwhile competition by other sources of fuel and power, together with economy in coal utilisation, the mechanisation of coal-getting and conveyance, closure of unprofitable pits and exhaustion of local measures, all proceeding at a time of severe economic depression, led to their own forms of unemployment which affected also the districts catering for the home market. The contraction of the industry thus widely, if unequally, spread over the coalfields was a stormy process involving great hardships to the miners and their families. One man in three was out of work during the worst years of the slump (fig. 1), and some mining localities suffered unemployment of two-thirds or more. Short-time working was common. Wages were low (fig. 2). Poverty, insecurity, and the frustrations of acute and chronic unemployment are thus at the root of this history.

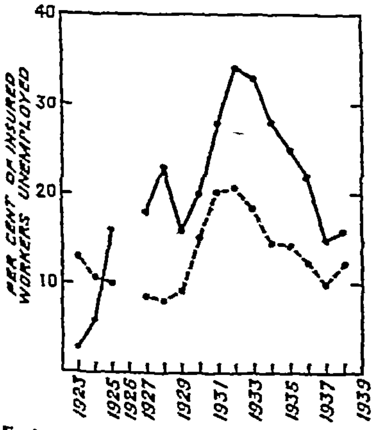

FIG. 1—Unemployment of coalminers (continuous line) and of other insured workers (interrupted line).[1 4 61]

Industrial Relations

The inter-war period opened with bitter disappointments for the miners. The Government set aside the majority recommendations of the Sankey Royal Commission that the industry should be nationalised and, instead, the mines were returned to their owners. In 1921, following drastic wage cuts, there was a three-month strike. During 1923–24 a temporary revival in the demand from abroad produced an artificial boom, and deceptive quiet in the coalfields. The years from 1925 onwards, however, were years of unceasing conflict open and suppressed, with the employers, "whose solution for slumping sales and profits took the form of an attack upon labour costs by the most simple and direct ways, the alteration of wages and hours"[9]; conflict that in the isolation of miners and mining villages "took on the character of a social war." The colliery owners were allowed by the Governments of the day "to win an unqualified victory," and the miners soon lost the fruits of many years of struggle—the national minimum wage and the seven-hour day. Industrial relations, always bad in coalmines, did not recover from this breakdown. Indeed, of the three broad phases in the history of labour relations—nineteenth-century master and man, early twentieth-century welfare and paternalism, and, now, the transition to cooperative participation—mining, it is fair to say, hardly shared in the middle phase at all. It was characteristic that the Government found it necessary to take more direct responsibility for the welfare of this than of any other industry; whence the great achievements of the Welfare Commission. The opacity of the owners to the needs of their dependants, as represented by Lord Londonderry's description of the industry as "the best managed in this country,"[29] aggravated the atmosphere of bitterness in the coalfields. Fig. 3 compares the incidence of disputes in coalmining with the rest of British industry.

A Dangerous Trade

The occupational hazards of coalmining are a permanent burden on the lives of miners and their families and form an essential part of the history of any period. A few figures must suffice to describe the magnitude of the problem and to compare the lot of coalminers with other workers. During 1938, the last year for which general statistics are available,[47] underground workers in coalmines had by far the worst record, about one man in five receiving compensation for accident or disease. Dock- and quarry-workers were next with about 10% affected, and surface mine-workers followed with 6½%, a rate substantially higher than for factories, constructional works, and railways. Fig. 4 shows that young persons were at even greater disadvantage than their elders. Table I deals in more detail with recent years to show what still remains to be done. Little progress was made throughout the inter-war period,[13 32 49a 49c] though fatal accidents have fallen by almost a half in the past few years.[55]

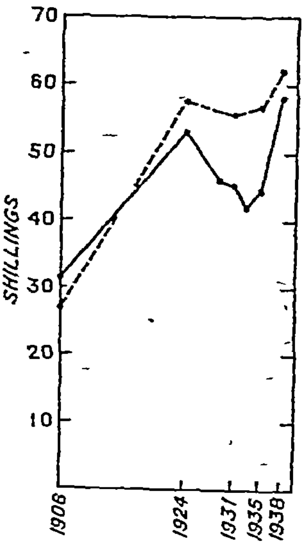

FIG. 2—Average weekly earnings of coalminers (continuous line) and of all male industrial workers (interrupted line). The figures for coalminers include cash value of allowances in kind.[5 22 27a 61]

* * *

Retreat from the Mines

The background of mining history between the two wars was made up of material privation and political defeat, along with the ever-present dangers of the trade. During those years the miners developed a discontent that was spiritual as well as economic.[23a] There was "a revolution in mining psychology. In place of the old pride of craft and pride in the industry, a revulsion of feeling has taken place against colliery life and colliery work."[19b] The miners reacted in what ways they could, in conflict with the employers as already seen, in a drift from the mines and mining districts, and in a determination that their children's future should lie elsewhere.

Population of Coalminers Falls

In 1920 almost 1,250,000 men were on the colliery books. From that year numbers fell, reaching 700,000 in 1941, about which figure they have since fluctuated.

Drift from Mining Districts

The population of England and Wales increased by about 10% during the inter-war years, mostly as a result of the superiority of birth-rates over death-rates. An attempt is made in fig. 5 to estimate the population trends in the five principal coalfields. It was possible to follow only two regions through till 1939; in the others extensive boundary changes cut short the inquiry. In each case the population trend was compared with that of the whole country over the same period. The coalfields, without exception, had an unsatisfactory record; and, though they also had higher birth-rates than death-rates, they did not enjoy the natural increase of their population that might have been expected. In Yorks, Derby, and Notts, and in the Midlands the rise in numbers was below the average; in the North East the population remained almost stationary; in Lancashire numbers actually fell; the exodus from South Wales reached the remarkable figure of 21%—miners were escaping, as one of their leaders wrote, from a "medley of patronage, charity-mongering and poverty,"[13] and this despite the high level of unemployment in other coalfields, in other industries, and in other parts of the country.

TABLE I—OCCUPATIONAL MORBIDITY AND MORTALITY AMONG COALMINERS [27b 55]

Year	1943	1944	1945
Man-power	708,000	710,000	709,000
Accidents:			
Incapacitating for over 3 days	173,716	176,847	181,059
"Serious"	2596	2553	2353
Fatal	713	623	550
Diseases:			
"Beats"	7478	7448	..
Nystagmus	2006	1809	..
"Dermatitis"*	1207	1506	1867
Pneumoconiosis	1322 (1278†)	2048†	5310†
Deaths from silicosis ..	276	311	387

* All miners, including some other than coalminers † South Wales

Young People Turn Away

These population movements affected especially the younger people. Despite an overall reduction of close on 40% in the past quarter-century, numbers over 35 years of age have hardly changed; but that of young persons is less than a third of what it was, and of the younger adults only a half. The reduction of young persons has proceeded sixteen times as fast as that of persons older than 35, and of younger adults nine times as fast. The age-distribution of the industry in 1945 was less favourable than will be that of the country as a whole in 1980, according to conservative estimates.[15 15a] Parallel to this movement, table II shows how, in the two regions (unfortunately not the most representative) where some estimate could be made, the decline of population was similarly dysgenic and was again due in disproportionate degree to the emigration of the young.

TABLE II—YOUNG MEN LEAVE THE MINING VILLAGES

Estimate of residuum, as indicated in the National Register,[56] of the cohorts aged 5–14 and 15–24 in 1921, males

—	1921	1939	Decline
Cohort aged 5–14 in 1921			
England and Wales	100%	87%	13%
Lancashire mining areas	100%	50%	50%
South Wales and Monmouth mining areas	100%	74%	26%
Cohort aged 15–24 in 1921			
England and Wales	100%	88%	12%
Lancashire mining areas	100%	60%	40%
South Wales and Monmouth mining areas	100%	67%	33%

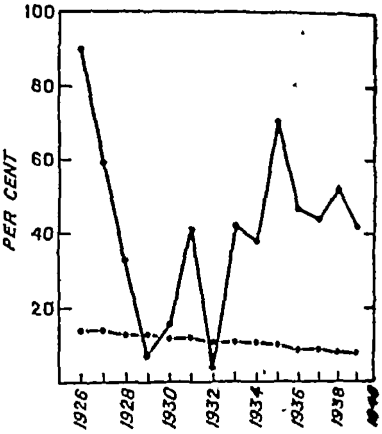

Fig. 3—Industrial disputes 1926–39: upper curve, proportion of all time lost which was lost by coalminers; lower curve, proportion of all insured workers who were coalminers.[54 61]

HEALTH OF COALMINERS

During the inter-war period miners had an unfavourable record in sickness and mortality. The Scottish reports[44] are the main source of information on the comparative morbidity of different occupational groups. Table III shows among the miners an abnormal load of incapacity due to acute and chronic sickness. Analysis shows that miners uniformly returned higher rates for all the commoner conditions. It would be interesting to inquire for each complaint why miners should be more affected than others. Much more interesting, however, is the evidence which this gross overall excess may provide of a psychological as well as physical dis-ease. Several authorities have commented on the high incidence of psychoneurosis and psychosomatic disturbances among miners,[10 17 25] and some have claimed that these increased between the two wars.[10 17] Unfortunately no data exist that would permit the separation of occupational from more general environmental influences which might have helped to produce such disorders or to increase their prevalence.

TABLE III—MORBIDITY OF MINERS IN SCOTLAND

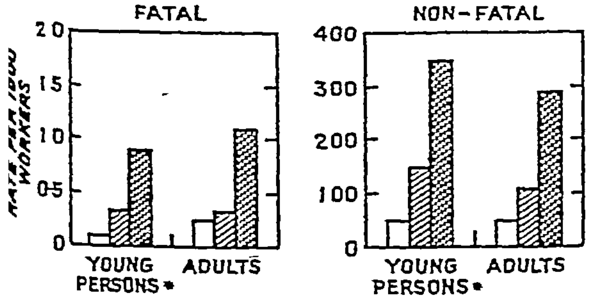
Occupational group	1930–33		1935–36
	Annual incidence of sickness (rate/1000)	Average duration of sickness (days/person)	Incidence of chronic sickness (rate/1000)
Miners	405	18·0	20
Other males in mining areas.. ..	189	8·5	..
All males less miners	190	8·7	..
All males	..	..	17

Differences in age structure were insubstantial at a count, 1933–34.

Deterioration in Trend of Mortality

The course of mortality among miners in recent years is of great interest in view of what has already been described. Death-rates are of value as a measure of healthiness; but deaths by accident form such a high proportion of the mortality of miners that total death-rates are unsatisfactory for this purpose. In the first place, therefore, death-rates from "natural" causes, excluding accidents, were calculated, and fig. 6 compares the progress among miners and other males; the scale used enables this to be done easily—equal vertical distances denote equal percentage changes. In 1890–92, 1900–02, and 1910–12 the mortality of miners under

5 years of age was substantially less than the others, nd during this time at the lower level had fallen, on the hole, as fast. From 1910–12, however, the curves iverge. Between 1910–12 and 1921–23 mortality in ther men under 24 remained at the pre-war level. nd in those aged 25–54 the steady decline continued; ut the miners under 44 registered an appreciable icrease, and those aged 45–54 a relatively small decline. n the latest period, from 1921–23 to 1930–32, the death-ates of other young men recovered sharply, whereas the eterioration among the miners persisted or was replaced y a negligible improvement. Among the adolescents ho illustrate these trends most clearly the death-ate from natural causes in 1930–32 was actually higher han in 1890–92. Miners, that is, participated to an ltogether exaggerated degree in the unsatisfactory end of mortality among young people between 1910–12 nd 1921–23; during the next ten years the trend among he miners was different from, and inferior to, that of the est of the population. Comparison of the rates of last entury and this is not altogether satisfactory, because f improvements in the Registrar-General's allocation of en to *occupations* and not merely to *industries*, though oalmining is one of the few instances where some omparison is justifiable.[40] In any event strictly com-parable *occupational* groups are available for 1910–32.



4—Industrial accidents in 1944 in coalmines and in factories: blank, factories; single hatching, mines (surface); double hatching, mines (underground).[42, 53]

* Miners, 1942–45, estimated.

In 1885 Farr's successor[37] remarked on the "surpris-ingly low" death-rates of miners and quoted a similar bservation made as far back as 1858. The explanation f this superiority, which lasted till 1930–32, probably ay in the traditional method of recruitment to the ines: "the weaker members of the population in mining areas are in practice excluded (from the industry) by the action of their parents who recognise that, while the mine may be the traditional, or at least a suitable career for their stronger and more robust children, some other occupation must be found for delicate members of the family."[49a] Many things may have contributed to the setback in the 1920's and 30's (which is analogous to some other unsatisfactory inter-war trends).[21, 23, 35] Its spread over many different causes of death, its occurrence among surface as well as underground workers, and the fact that it was most prominent in the youngest age-group, was irregularly related to later ages, and was seen not at all in the oldest make it unlikely that occupa-tional causes were responsible. More probably, other forces were at work: less healthy recruitment to the industry, and emigration of the healthier from it. Its waning attractions in these years may have induced a departure from the traditional practice to recruit the fitter youngsters to the mine. There was, in any case, a considerable dilution of mining labour during the 1914–18 war. Between 1921 and 1932 many young miners, particularly young hewers and getters, left the industry: the fitter among these, again, may well have been the readier to leave.[40]

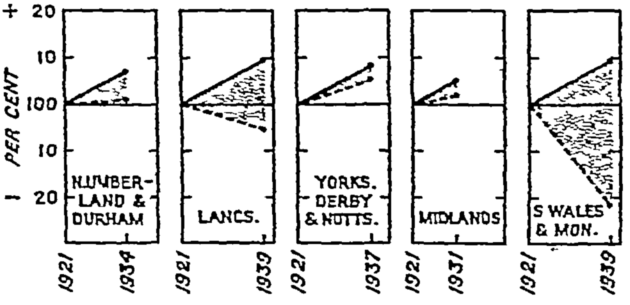


Fig. 5—Population of coalfields in inter-war period. A coalmining area was defined as an area which at the census of 1921 had over half its employed males employed in coalmining. The continuous lines represent the population trend of England and Wales, the interrupted lines represent the trends in the coalfields; the stippled areas represent the deficits in the coalfields.[34a, 35b]

DECLINING BIRTH-RATE IN MINING COMMUNITIES

Finally, the changes in the birth-rate of mining communities should be seen in their social and economic setting. The period under review saw a steady fall in the national birth-rate, but this was particularly heavy in the mining districts, where birth-rates fell by about a third more than the national average. Such crude rates are liable to be misleading in view of the selec-tive emigration of younger people from the coalfields. Martin[31, 31a] investigated the (legitimate) "fertility" of mining and other districts from 1860 to 1932, relating births to the female population of childbearing age. He found that the mining districts had the highest fertility-rates between 1860 and 1892, and the least decline during those years; they had the highest rate also in 1910–12 but the greatest decline, over 40%, between then and 1930–32. In fact, this decline occurred mostly between 1920–22 and 1930–32. Innes[24] found that the reduction in this decade was particularly well marked in the families of the semi-skilled miners, whose birth-rate fell by half.

SUMMING-UP THE INTER-WAR PERIOD

The pattern of the miners' history in the twenty years between the wars was made up of the related and interacting elements of low living standards, ill health, conflict, and withdrawal. Coalminers were a depressed class. Wages ranked 82nd among the

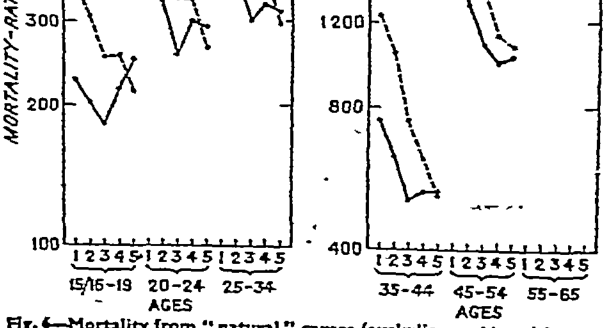

Fig. 6—Mortality from "natural" causes (excluding accidents) in coal-miners and in other men. Semi-logarithmic scale.[40] Continuous lines represent coalminers; interrupted lines, all other men. 1 = 1890–92; 2 = 1900–02; 3 = 1910–12; 4 = 1921–23; 5 = 1930–32.

country's industries, even after their rise late in the 1930's.[61] During much of this period most miners, though over half were reckoned as skilled workers and none as unskilled, whether in work or out of it, on full time or short time, could not provide their families with the minimal needs for healthy living.[26] Miners' infants in 1930–32 had a death-rate 32% higher than that of the infants of other workers [41]; in 1939 the excess was 37%.[39] The (standardised) mortality of miners' wives, young and middle-aged, in 1930–32 was 27% worse than that of other working-class wives. The most important group, the wives of the skilled hewers and getters, recorded at 20–45 years of age one and a quarter times the rate of the rest of their own social class in mortality from puerperal causes, almost one and a half times for respiratory tuberculosis, and almost twice for (rheumatic) heart disease.[41] The miners themselves, relative to other men, had regressive mortality trends, and they had four times their share in compensatable disease and accident, and, as far as information is available, twice the sickness of other workers. Disputes amounted to over 260,000,000 days, two-thirds of the total lost in the country, though miners were about 10% of the labour force.[1 54 61] The unpleasant features of the work, the poor and uncertain living it offered, the squalor of the villages in the depressed areas, the chronic state of war with the owners, all combined to put off new entrants: "I had four boys," said a miners' leader,[19a] "and . . . I would sacrifice anything rather than allow any of my boys to enter the industry." The severance of this traditional link between mining families and the mines, the shrinking number of miners, the loss of population from the mining districts, with the break-up of family life that this involved, represent a large-scale withdrawal from the industry. And "withdrawal," operating at deeper levels, may be a common factor of these more obvious responses and of others more subtle, the excessive illness, the psychosomatic reactions, the deteriorating mortality, and the declining birth-rate.

* * *

Continuing Effects: the War and Since

The coal industry entered the war 1939–45 unprepared for the struggle that lay ahead: the miners burdened with a store of unhappy, but soon to be irrelevant, memories; the owners unwilling to discard long outworn modes of thought. Conditions in the industry were transformed in the course of the next few years. Wages rose, though slowly at first, and by 1945 were twice the 1938–39 level. At the instigation of the Government great advances were made in the organisation of training, welfare, safety, health, and rehabilitation. Yet coalmining was a constant source of trouble on the home front, with excessive absenteeism and recurrent strikes which were out of keeping with the spirit and needs of the time.

More serious, and ironic commentary on the record described, by 1941 there was no longer any question of *un*employment and, soon after, there developed an actual shortage of man-power in relation to needs. The community suddenly awoke to the importance of the miner in its life. There was much "prestige" talk, and coalmining was put on a par with the Armed Forces as a form of national service. But this belated recognition did not carry conviction with the mining community; it failed, at any rate, to overcome the forces that had been maturing in the previous twenty years and could now, with war and booming employment, for the first time achieve full expression. Juvenile recruitment reached new low levels, numbers under 18 years of age falling from 70,000 in 1938 to 34,000 in 1945; these youngsters were insufficient to fill half the places rendered vacant by miners who died, retired, or were "freed" because of sickness and disablement. Most significant of all, perhaps, examination of the war-time fluctuations in the age-distribution of the industry [55] suggests that a disproportionate part of the small army who left for "medical" reasons were younger men. Many miners joined the Forces, in particular when the collapse of France temporarily reduced the demand for coal, and later had to be conscribed back; many left for other occupations. "Were it not for the operation of the Essential Work Order," said a Member of Parliament from a coalfield which was relatively prosperous in the inter-war years, "there would be an exodus from the industry greater than that of the children of Israel from Egypt."[18] "The main prop of the industry's man-power (became) the State's action in directing unwilling men, ex-miners, and Bevin boys into an industry which no power short of State direction would have made them enter."[61] The Bevin boys shared the repulsion felt by the community at large; they entered without enthusiasm, and it has been estimated that only about 1% of them intended to remain in the industry.[2]

This difficulty in recruiting man-power epitomises the social problem of the industry today. It is, in effect, the delayed and cumulative consequence of the quarter-century of history which has been examined. Recently, with nationalisation and the five-day week, and in response to the dire shortages of the fuel crisis of February 1947, the number of recruits, both juveniles and ex-miners, has improved. As yet, however, there is no evidence that a final solution has been found. The miners, sensibly enough, consider recruitment will only reach satisfactory levels when coalmining can offer attractions compatible with the most progressive of other industries. There is no doubt that medicine with its many disciplines could contribute more than it has done in eliminating some of the unattractive features of the industry, and could help to increase the well-being of miners and mining communities. Equally, medicine should be concerned with the larger questions of social health that are raised by this problem.

* * *

Medical Relations

The first need is for organisation. The case for a special association of medicine with mining has been demonstrated; as yet this association is poorly developed. The mining areas were at a disadvantage before the war when competing in the money market which, for the most part, determined the distribution of doctors. In consequence, they were served, almost without exception, by less than the national average of 1 doctor per 1000 of population, and many by less than 1 doctor for 5000.[30] Hospital facilities were often on a similarly inadequate scale, as the hospital surveys have shown.[33] Occupational health services were deficient in most industries before the war; in conformity with what has already been seen of coalmining this industry was among the backward.

Recent legislation should improve this situation, though the reforms in local-government finance which are yet to come will be almost as important as the National Health Service Act. Responsibility for industrial health now lies with the Ministry of Fuel and Power and the National Coal Board, and funds should also be available under the National Insurance (Industrial Injuries) Act. The workers, moreover, are deeply interested: the unions, for instance, now support pre-entry medical examinations which they opposed before the war.[49b]

The Need for Knowledge

Information on many of the medical aspects of this industry is urgently needed. On the physiological side, for example, the nutritional requirements for optimal output are not yet settled,[28b] and the changing relations of hours, shifts, output, absenteeism, and fatigue deserve tinuing investigation. The idea so strongly held by ners that they are "past their best" at 35 requires partial examination. A job analysis of the industry uld be carried out; and if, when work is fully chanised, it still remains true that miners in their ies or even forties are "old," the case for the diversi-ation of industry in the mining villages will become n more pressing. Apart from some rather conflicting dence on the greater liability of older men to acci-nts,[19f, 59] particularly at high temperatures,[59] there little to go on. As regards morbidity, there will be portunity for a fresh start soon, nationally and locally; d, in view of the importance of verifying and bringing to date the pre-war Scottish figures, this industry ght be selected for prior attention. (Some recent all-scale surveys have controverted the Scottish dings and suggest that miners are particularly lthy.[33]) Among occupational disorders, only pneumo-iosis is receiving at present the attention it deserves, ugh major recommendations of the 1944 Advisory mmittee remain to be implemented.[42] The problem the "beat" diseases needs restating; there is nothing the report of the Medical Research Council's inquiry er the war of 1914–18 [22b] to suggest that it need have oved so refractory—and in the interval the oppor-nities for prophylaxis have increased as pit-head ths have multiplied, first-aid organisation has improved, d chemotherapy has developed. Meanwhile, though e proportion of thinner seams, in whose working these eases tend to occur, is rising, protection of knee and ow with pads, &c., is not compulsory. "Fibrositis" so much commoner among miners [16] that it might most be included among the occupational disorders. far it has been little studied in relation either to ysical conditions underground or to washing and ying facilities. "Dermatitis" has increased seven-ld during the war,[6] though it is not known whether is is a real increase or not. Occupational and social ass death-rates are unlikely to be available for another n years. The possibility of anticipating the next ecennial Supplement by sample studies of infant ortality in mining communities and of the mortality ends of miners should therefore be considered.

The past twenty years have seen a great advance in e understanding of psychosomatic disorders, but little tention has been paid in this country to nystagmus, hich, surprisingly, is commoner again after its decline the 1930's. It would be revealing to know the istribution of the new cases and how many are in x-miners. Among psychological aspects, however, pplication of the theory and knowledge of accident-roneness is most urgent. (In general, coalmining cidents, which should be a major preoccupation of dustrial medical research in this country today, are ather neglected.) Several problems in the field of indus-rial psychology demand attention: the special quali-cations of management, above and below ground; the most effective methods for developing the mine as a coöperative effort; and, equally important perhaps, the elations to output of systems of payment that are a onstant irritant [8] might be investigated. The psycho-ogical implications of mechanisation in personnel election and in counteracting the new tensions it intro-duces,[56] also await exploration. The career which the industry is already offering the new entrant is that of ngineer. "Under certain conditions," it has been said, "machinery can make a colliery a mechanised hell." [19c] If there is any truth in this sort of statement, it is medicine's business to intervene in good time.

A Miner Medical Service

Whatever the future will bring in other industries, and elsewhere in this industry, there is already a more than sufficient case for the establishment by the State of an industrial-health service for coalminers in South Wales. The usual functions in placement, environmental hygiene, and accident prevention need to be carried out. Coöperation of the workers in the many protective measures must be assured; and since the Davy lamp was introduced it has been known [16] that this cannot be assumed but demands intensive education, in which the health service should surely be of the greatest usefulness. In South Wales periodic radiological and clinical examinations in relation to working conditions need to be instituted, together with a follow-up of disabled workers. Such steps, as much as the perfection of dust suppression, will be necessary if public confidence in the industry is to be restored. South Wales has suffered the greatest losses in man-power, and recruitment there lags behind the national average, despite the absence of alternative employment in the valleys and the relatively high unemployment there. Resettlement is a general problem, though most acute also in South Wales. Rehabilitation of injured men is now a highly organised service, but the arrangements for the resettlement of the disabled are inadequate. There is no worse advertisement for the industry than the derelicts with nystagmus, old injuries, silicosis, and now pneumoconiosis, who hang around the street corners and labour exchanges of the mining villages.[20a, 20b] The Government have the machinery to provide employment, but the sense of urgency seems to be lacking.[20a] If many of these men are to find work again in the industry, a complete job analysis becomes all the more necessary.

A School of Mining Medicine

It is clear that a many-sided attack on the medical problems of the industry is needed. The suggestion has been made that research and teaching might gain by being centred in an appropriate institution.[26a, 51]

The Young Miner

The record of the young miner has been even less happy than that of his elders. Youngsters have been unwilling to become miners, particularly underground workers,[45] either in the progressive mechanised coalfields or in the more backward ones. When enrolled they have displayed high rates of sickness, accident, absenteeism, and wastage. The retreat from the industry has been in large measure a withdrawal by the young. Combined operations by workers from a school of mining medicine might be of great help in adapting this ancient industry to the needs of the youth of today. Meanwhile Great Britain lags behind other countries, who have prohibited the employment of adolescents underground.[34]

* * *

Larger Issues

Recruitment

Our dilemma is simple. With full employment it is difficult to attract recruits to a "dark, dangerous, and dirty" [191] trade like coalmining; unless the number of coalminers is increased there will be no full employment. The traditional reservoir of mining labour has been the mining village. Today "the mining community is not willing to accept a special responsibility for the supply of new mining labour." [33] Hitherto miners, the mines, and mining villages have tended to form a closed system within our society. The extension of recruiting to the whole community is therefore a healthy development.

Immediate Remedies

The short-term approach to this challenge is to offer material and economic inducements, and the Government have accepted this principle, if rather half-heartedly and rather late. Coalmining is still only 16th on the industrial wage ladder, but there is now a tendency, at least, to regard it as a "most favoured" industry. There is evidence, however, of much muddled thinking in public discussion of these issues. To give all men, whatever their work, the *same* rations, for example, may be convenient, but physiologically it is not equitable.

Short-term policies need not be mere expedients. The Government have promised the mining districts some priority in housing, and this can inaugurate the long-term programmes that are needed for what is unlikely to be a short-term difficulty. The country has paid little attention to the general "uncivilisation"[60] of its mining villages. Yet, in the long run, this is likely to matter as much as the need for relieving the congestion of London. It is a common criticism of miners that they are sometimes content with less than they might earn, and absenteeism has often been ascribed to this. It is difficult to say whether there is any truth in the claim, or if it belongs to the mythology, often politically inspired, which envelops the industry. But if a clue were needed to the explanation of such limited needs and restricted horizons it might well be found in the present character of the mining village.[3]

STATUS OF THE MINER

Mining offers its workers many satisfactions in its purposeful and successful struggle with nature. But here, as elsewhere, prestige and the regard of others is a condition of contentment.

> "The fundamental problem is to raise the status of the industry in the public mind. Its neglect between the wars went so far that miners were often held in contempt by other workers and came to feel themselves the whipping-boys of industry. Miners' sons found work elsewhere to secure self-respect and standing in the eyes of their fellow men—and women."[58]

Some of the factors in the decline of the miner's status have been described in the first sections of this paper; but other and deeper issues were involved. During the inter-war period the forces making for social change were acting against such trades as mining. The community, including the workers, increasingly adopted the values of its lower middle classes; and the "little man" of those days did not wield a pick and shovel. This development was an outcome of 150 years during which labour had been "alienated" from the ownership and control of industry and in which the way of life of the employers had become separate and far removed from that of the men who did the manual work and dirty jobs. In this sense the adoption of lower-middle-class standards represented a movement upwards. The movement of ideas was promoted by a genuine and widespread misunderstanding of the changes which were taking place in society. There was some swing from primary production to distribution, personal services, and "tertiary" industries; some decline of craftsmanship; and a growth of technical and white-collar grades; but their extent was greatly overrated.[11]

In mining this problem of status is not new: "We are an insulted, oppressed and degraded body of men," complained a miners' leader 100 years ago; "miners as a class are not looked on with respect by the public . . . we have had no respect for ourselves."[14] It originated in the peculiar derivation of a great industry not from ancient crafts with a guild organisation but from a later and semi-slave system.[50] During the second half of the nineteenth century the miner's status improved, but in the 1920's and 30's it deteriorated again. The community has now awakened to the importance of this industry to its survival, and nationalisation provides an opportunity for reform. In so far as status depends on material security, much has already been done, and more will be; but equally urgent is the other approach that is now open. The status of an industry rises as it acquires the character of a "profession"—i.e., it can regulate entry and training, has codes of conduct and standards of performance and responsibility for observance. In view of the backwardness of coalmining an acceleration of development in this direction may be as important to its future as the assurance of its living standards and its transformation into an "engineering" industry. The need for the development of a more "professional" status is not restricted to coalmining, and it involves more than the relative attractiveness of any industry. It involves, for example, the methods to be adopted in attaining maximum output and the whole question of industrial discipline in a society with full employment and social security. Tawney, with remarkable foresight, has anticipated these difficulties." "Collectivism by itself," he wrote 25 years ago, "is too simple a solution"; if the public is to get efficient service, industry must be carried on with the active coöperation of the organisation of producers. Coöperation involves responsibility of the workers for maintaining and improving the character of the service. And responsibility involves power—the power of the workers' associations to enforce upon their members the obligations of their craft.

In the last analysis, however, the problem of status can only be partly solved by reforms within an industry, including in this instance its increasing mechanisation. The community as a whole must either discard an irrational, antisocial, and now positively dangerous prestige system, or this country cannot survive as a great power, certainly not as a free power. The alternatives are either a more healthy scale of social values, or economic disaster, from which conscription of labour or the importation of foreign labour is unlikely to save us. The social sciences, social medicine included, can surely help us to understand this very real sickness of our society; and with understanding can come, for the first time, a conscious attempt at control and cure.

I am grateful to the Statistics Branch of the Ministry of Fuel and Power for help.

PENICILLIN AS AN AID IN PROSTATECTOMY *

J. G. YATES BELL
M.B. Lond., F.R.C.S.
UROLOGICAL SURGEON, KING'S COLLEGE HOSPITAL, LONDON

THE value of chemotherapy and penicillin in the atment of infections after surgery of the prostate nd is well recognised and established with a gratifying ver mortality in all operations. It is recognised also t the mortality before prostatectomy (including doscopic methods) remains high, probably over 15% ey 1945), and that death is almost invariably the result infection.

Power (1946) considers that the prophylactic prerative administration of penicillin, combined with the llin operation, has revolutionised prostatic surgery. I ve had the good fortune to have penicillin available these cases from 1945, and hope to show that penicillin a prophylactic can lower the preprostatectomy rtality.

Hæmorrhage has for some time ceased to be the gbear of prostatic surgery, with the adoption of the rris operation. In most surgeons' hands the best ures were from the two-stage operation, but this rries with it a high mortality for the suprapubic stotomy. Further, there was a definite morbidity-rate om sepsis, which usually took the form of urinary fection, including urethritis, from the long use of an dwelling catheter, which might later produce a stricre. Rarer complications include osteochondritis of the mphysis pubis (in 4 of my patients), a most distressing condition requiring some four months' recumbency before the patient can begin to walk. It probably does not arise, as Riches (1946) has suggested, from injury of the periosteum at operation, but from a lymphatic spread from a low-grade pelvic cellulitis. In one of my cases the osteochondritis developed three months after the operation, two months after the patient had returned home. Osteochondritis may also arise in the tuber ischii (2 of my cases) and then could only be lymphatic in origin.

The newer operations of Hey (1945) and Millin (1945) have been welcomed because, while controlling hæmorrhage at least as well as a Harris, both of them have reduced the postoperative morbidity-rate; and, though neither is an easy operation, both of them are safer than the Harris in cases of difficulty, such as profuse bleeding when a ureter may be included in the trigonal stitch. It may therefore be instructive to consider, for each operation, possible reasons for the lowered morbidity.

The Millin operation, including either wedge-resection or stitching down of the trigonal flap, which is essential to prevent bladder-neck obstruction (Millin 1946), has a very short period of indwelling catheter and no deep sutures through the pelvic cellular planes.

Hey's operation also has a very short period for the indwelling catheter and no stitches through the pelvic fascia, hæmostasis being obtained by diathermy coagulation.

Hey strongly emphasised the risks of cystoscopy, catheterisation, and suprapubic cystostomy in causing preoperative infection and high mortality, and he was the first to affirm that uræmia does not often develop except secondarily to pyelonephritis (and sometimes secondarily to a low blood-pressure, such as might result from auricular fibrillation). Renal function therefore is important only in that pyelonephritis is more severe when kidney tissue is already damaged. Hey draws attention to the very high preprostatectomy mortality in most hospitals and claims that his aseptic operation cuts out this mortality by excluding infection without increasing his mortality for the major operation: in fact his figures compare well with statistics for prostatectomy in selected cases. This, however, is achieved by excluding cystoscopy, whereby the commonly associated bladder lesions (papilloma, carcinoma, stones, &c.) might be discovered before operation and more information obtained about the suitability of the gland for removal or endoscopic resection. The exclusion of catheterisation for acute retention may mean the loss of a valuable week or fortnight in which a fibrillating heart could be treated or remedial exercises given to the chesty subject; these measures are often highly beneficial in the less urgent case and are likely to be even more valuable in patients with acute retention, provided always that infection is not introduced.

PROPHYLACTIC PENICILLIN

In an attempt to lower the preoperative mortality, while permitting catheter drainage and cystoscopy to be carried out, I tried penicillin as a prophylactic. It was hoped that preliminary cystostomy could be avoided, in view of its high mortality and the additional disadvantages of a long stay in hospital, some increase in the technical difficulty of all second-stage operations, and the discomfort of the patient.

The first point to be decided was the dosage suitable for routine use in all cases. The concentration of penicillin in the urine was estimated after various doses, and the figures obtained were correlated with renal function tests in each patient. It was obvious that different doses would be required to produce the same concentration in patients with different degrees of renal function, but for practical purposes it seemed wise to

in public discussion of these issues. To give all men, whatever their work, the *same* rations, for example, may be convenient, but physiologically it is not equitable.

Short-term policies need not be mere expedients. The Government have promised the mining districts some priority in housing, and this can inaugurate the long-term programmes that are needed for what is unlikely to be a short-term difficulty. The country has paid little attention to the general "uncivilisation" [60] of its mining villages. Yet, in the long run, this is likely to matter as much as the need for relieving the congestion of London. It is a common criticism of miners that they are sometimes content with less than they might earn, and absenteeism has often been ascribed to this. It is difficult to say whether there is any truth in the claim, or if it belongs to the mythology, often politically inspired, which envelops the industry. But if a clue were needed to the explanation of such limited needs and restricted horizons it might well be found in the present character of the mining village.[8]

STATUS OF THE MINER

Mining offers its workers many satisfactions in its purposeful and successful struggle with nature. But here, as elsewhere, prestige and the regard of others is a condition of contentment.

> "The fundamental problem is to raise the status of the industry in the public mind. Its neglect between the wars went so far that miners were often held in contempt by other workers and came to feel themselves the whipping-boys of industry. Miners' sons found work elsewhere to secure self-respect and standing in the eyes of their fellow men—and women." [58]

Some of the factors in the decline of the miner's status have been described in the first sections of this paper; but other and deeper issues were involved. During the inter-war period the forces making for social change were acting against such trades as mining. The community, including the workers, increasingly adopted the values of its lower middle classes; and the "little man" of those days did not wield a pick and shovel. This development was an outcome of 150 years during which labour had been "alienated" from the ownership and control of industry and in which the way of life of the employers had become separate and far removed from that of the men who did the manual work and dirty jobs. In this sense the adoption of lower-middle-class standards represented a movement upwards. The movement of ideas was promoted by a genuine and widespread misunderstanding of the changes which were taking place in society. There was some swing from primary production to distribution, personal services, and "tertiary" industries; some decline of craftsmanship; and a growth of technical and white-collar grades; but their extent was greatly overrated.[11]

In mining this problem of status is not new: "We are an insulted, oppressed and degraded body of men," complained a miners' leader 100 years ago; "miners as a class are not looked on with respect by the public . . . we have had no respect for ourselves." [14] It originated in the peculiar derivation of a great industry not from ancient crafts with a guild organisation but from a later and semi-slave system.[50] During the second half of the nineteenth century the miner's status improved, but in the 1920's and 30's it deteriorated again. The community has now awakened to the importance of this industry to its survival, and nationalisation provides an opportunity for reform. In so far as status depends on material security, much has already been done, and more will be; but equally urgent is the other approach that is now open. The status of an industry rises as it acquires the character of a "profession"—i.e., it can regulate entry and training, has codes of conduct and standards of performance and responsibility for observance. In view of the backwardness of an acceleration of development in this direction may be as important to its future as the assurance of its living standards and its transformation into an "engineering" industry. The need for the development of a more "professional" status is not restricted to coalmining, and it involves more than the relative attractiveness of any industry. It involves, for example, the methods to be adopted in attaining maximum output and the whole question of industrial discipline in a society with full employment and social security. Tawney, with able foresight, has anticipated these difficulties. "Collectivism by itself," he wrote 25 years ago, "is too simple a solution"; *if the public is to get* efficient service, industry must be carried on with the active coöperation of the organisation of producers. Coöpera-tion involves responsibility of the workers for and improving the character of the service. responsibility involves power—the power of the workers' associations to enforce upon their members the obligations of their craft.

In the last analysis, however, the problem of status can only be partly solved by reforms within an industry, including in this instance its increasing mechanisation. The community as a whole must either discard its irrational, antisocial, and now positively dangerous prestige system, or this country cannot survive as a great power, certainly not as a free power. The alternatives are either a more healthy scale of social values, or economic disaster, from which conscription of labour or the importation of foreign labour is unlikely to save us. The social sciences, social medicine included, can surely help us to understand this very real sickness of our society; and with understanding can come, for the first time, a conscious attempt at control and cure.

I am grateful to the Statistics Branch of the Ministry of Fuel and Power for help.

Continued at foot of next page

cystostomy was left in only 0 9% of cases whereas previously 10·4% of all patients with simple enlargement d not have a prostatectomy after drainage, either ause they died, or because they could not be made for another operation.

From a mechanical point of view, drainage by urethral heter (of the five-eyed Tieman type) is as satisfactory by suprapubic tube. The limitation to drainage by e urethral catheter in the past was the short period er which it could be used without the development urinary infection. This limitation is almost entirely moved by the use of penicillin. In only a very few es was cystostomy needed when penicillin was used. nsequently one-stage operations, which are more isfactory to both patient and surgeon, can be done more often.

The points already put forward are further emphasised the postoperative mortality and morbidity. The uses of death in all groups of cases in which penicillin e not used show clearly that most patients die from emia consequent on an ascending pyelonephritis, as y (1945) has contended. A difficulty met with in alysing causes of death from a series of case-records that many patients die from some concurrent disease e.g., coronary or cerebral thrombosis—while they are æmic and have a urinary infection. In the following alysis deaths due to extra-urinary conditions are ssified separately, even if the patient had uræmia at e same time:

Uræmia and pyelonephritis	43
Malignant cachexia	8
Pulmonary œdema	3
Paralytic ileus	3
Hæmatemesis	3
Coronary thrombosis	2
Cerebral thrombosis	2
Pulmonary embolism	2
Empyema	1
Chronic renal disease	1
Pyelonephritis	1
Sulphapyridine anuria	1
Hæmorrhage	1
Anæsthetic	1
	72

Of the 72 deaths when penicillin was not used 44 ere attributable to pyelonephritis; undoubtedly many these would be avoided under the present system. onchopneumonia was not recorded as a cause of eath in any case. It often occurred but was invariably condary to urinary infection or some other more portant condition.

With penicillin there were only 8 deaths, and in only of them could pyelonephritis be said to have been the rect cause. This man had a twelve years' history nd was heavily infected (temperature 101°F) on admission. He was drained with an indwelling urethral atheter and given penicillin for two weeks. After a ne-stage Harris prostatectomy he ran a high fever (up o 103°F) and died of uræmia on the fourteenth day fter operation. In reviewing the case it has been ecided that had drainage and penicillin been continued a longer period (say three or four weeks) the man would have survived. This, then, is not so much a ailure of penicillin as a failure to use drainage and enicillin long enough.

The other fatal cases during the penicillin period are instructive. One man had complete heart-block and diabetes ellitus. He died after nine weeks' catheter drainage, no peration being performed because of his general condition. It was suspected that pyelonephritis and uræmia would have been the ultimate condition causing death, but surprisingly necropsy did not reveal any evidence of gross renal infection; this undoubtedly being due to the fact that penicillin was used. Two of the deaths following retropubic prostatectomy were the result of errors in technique mentioned above. The third patient died from morphine idiosyncrasy. In two of these cases necropsy revealed a surprising absence of pyelonephritis. One who had undergone resection died of bronchopneumonia. The seventh patient had a secondary hæmorrhage following transurethral resection, the treatment of which needed three anæsthetics in forty-eight hours. The man was a publican and died of circulatory failure. In the last case, a carcinoma of prostate, the patient collapsed with a dilated heart soon after his return to the ward.

The cases in which penicillin was used showed much less postoperative morbidity than did the earlier group. Only a very few cases presented the old-fashioned problem of the leaking suprapubic wound. Modern methods of prostatectomy have gone far to ensure this by their improved technique, but it is probably fair to attribute to penicillin a proportion of the success which has been attained in the recent series since it eliminates wound infection. In the few cases in which a fistula did develop penicillin allowed the use of an indwelling urethral catheter for ten days or more, by which time the wound healed well. This point is well emphasised by the methods used in closing suprapubic fistulæ in traumatic paraplegia. In some instances there was great difficulty in getting the abdominal wall to heal, and on occasion the fistula had to be excised and sutured; after a further period of catheter drainage it was possible to get all these wounds to heal. This process was invariably slow, and a catheter has been used many times for several months (being changed every fifth day) without recurrent flares of urinary infection. Again a few cases of traumatic paraplegia were treated with an indwelling catheter from the onset without having cystostomy. The catheter was left in place until some form of automatic micturition was re-established. The success in both these types of cases is attributed to the prophylactic use of penicillin.

Another disadvantage of the catheter is the possibility of urethritis, with the late development of a urethral stricture. It is too early to give figures for the incidence of stricture, but it is very rare to see signs of urethritis when penicillin is being used. No longer is it common to find pus caked round the meatus and catheter.

No attempt was made to discharge the prostatic patients from hospital early, and figures for the time spent in hospital after operation are of little value. This is particularly the case in this series, since most of the patients were treated in an E.M.S. hospital and were discharged on a weekly convoy.

ROUTINE TREATMENT

The lessons of these investigations have led to the following routine for prostatic obstruction, allowing for individual variations called for by special circumstances.

Patients with acute retention are admitted to hospital preferably without prior catheterisation; a five-eyed Tieman catheter is passed and tied in and the bladder emptied; slow decompression as a risk of renal failure is ignored, but very rapid emptying is avoided owing to the danger of bleeding—about an hour is allowed. Penicillin 20,000 units is given four-hourly for two days, and afterwards six-hourly as long as the catheter remains in situ †; should pyrexia develop, the penicillin is given three-hourly for a while in conjunction with a course of sulphadiazine. Great attention is paid to satisfactory mechanical drainage by the catheter, which must be inspected twice a day by the house-surgeon to prevent obstruction. Breathing-exercises are started, smoking is controlled, and the patient is assessed clinically as regards his suitability for resection or removal of the gland. Intravenous pyelography is important as a select a dose high enough to give an effective concentration in all cases. As a result of trials a routine dosage of 20,000 units of penicillin intramuscularly every six hours was chosen. It must be remembered that most men with enlarged prostates have a relatively poor renal function, so a greater interval can be allowed between doses than would be necessary in normal people, because the delay in excretion helps to maintain the penicillin level in the urine.

---

† More recently 200,000 units eight-hourly has been found equally efficient and less disturbing to the patient (Peeney 1947).

TABLE I—MORTALITY IN CASES OF PROSTATIC OBSTRUCTION TREATED WITHOUT AND WITH PENICILLIN

Treatment	No. of cases	No. of deaths
All cases, including carcinoma:		
No penicillin	608	72 (*14·1*%)
Penicillin	217	8 (*3·7*%)
Cases of simple enlargement:		
No penicillin	433	49 (*11·3*%)
Penicillin	192	6 (*3·1*%)

Once this basic dose had been decided on, all patients with an indwelling urethral catheter were given penicillin routinely as long as the catheter was in place. This was continued into the postoperative period until the catheter was removed or the temperature normal. With a few exceptions this was the principle used in the present series of 217 cases. If the temperature was over 100°F for more than forty-eight hours, the penicillin was given in larger doses, and this treatment was supplemented with one of the sulphonamides. In this way it seemed possible to control the great majority of urinary infections.

The combined use of penicillin with sulphonamides is of the greatest importance. It is often found that a man with an indwelling catheter who is having penicillin will, after being afebrile for four or five days, suddenly develop a temperature of 101° or 102°F. Culture of the urine at this stage invariably shows a good growth of coliform organisms. This can be quickly and easily dealt with by a short course (30 g.) of a sulphonamide. Recurrences of coliform infections at short intervals in these circumstances are not common.

There are other possible reasons why the penicillin itself is of great value in the prevention of infection. The concentration attained in the urine is high enough to prevent the penicillin from being totally destroyed if *Bact. coli* are present, and some strains of *Bact. coli* are sensitive to penicillin in this concentration. A culture of the urine of a man with an indwelling catheter and a urinary infection most often shows an overwhelming growth of coliform organisms, but other organisms, more sensitive to penicillin, may be responsible for maintaining the infection; if these are removed by penicillin the bladder may become more capable of dealing with the coliforms. This is particularly likely since the bladder is relatively resistant to infection by coliform organisms in pure culture and in many cases, if the history is long, will have developed a local immunity to them.

RESULTS

In the figures given below, the mortality and cystostomy rates substantiate clearly the claims which have been made. Further, the temperature charts of the series show a remarkably quieter course in the group in which penicillin has been used. Unfortunately it is impossible to standardise the degree of preoperative and postoperative fever and so illustrate this point with figures, but it has been noted time and time again. Also, though again no figures are available, postoperative chest complications have been far less severe in the penicillin group.

The cases fall into two main groups. In neither was any selection made, and all cases of prostatic obstruction under my care, whether in general or private practice, have been included. The first group, consisting of 508 cases (both simple enlargement and carcinoma), were treated between November, 1939, and November, 1945, during which time penicillin was not used. The second group, of 217 cases, fall between November, 1945, and June, 1947, and in all of them penicillin was used on the principles described above. Table I illustrates the great improvement in mortality.

Table I is concerned with the mortality of all cases admitted during the given period and is not merely the mortality after surgical operation. The cases are analysed further in table II, in which the mortality for all different forms of treatment is given.

Table I shows that the total mortality in all cases of simple enlargement fell from 11·3% to 3·1% after the introduction of penicillin. The mortality after operation in simple enlargement fell to a similar extent. Table II shows that of 189 patients operated on and treated with penicillin 5 (2·6%) died. This series includes 57 patients treated by retropubic prostatectomy of whom 3 died. Two of these deaths can be attributed to technical *failures (postprostatectomy obstruction due to not* excising the V) in the early stages of trying out a new operation, so it is probably fair to exclude them. If this is done, the mortality in operation cases treated with penicillin becomes 2·1%, which is a satisfactory reduction from the 5% without penicillin. The mortality in one-stage Harris prostatectomy fell from 9·7% in 72 cases to 2·6% in 38 cases; the numbers are small for such comparisons, but the mortality for transurethral resection is also slightly lower in the penicillin group.

In table II no account has been taken of the cases in which cystostomy was the sole operation done (though they are included in the mortality figures given above), because they give a misleading impression unless cases in which cystostomy was followed by prostatectomy or by transurethral resection are included. In the first period 160 (36·9%) of 433 patients had cystostomies, and 24 (15%) died. In 45 of the 433 cases cystostomy was the only operation performed, because either the patient died or he was unfit for further operation. In the second period, out of 192 cases only 21 (10·9%) had cystostomies, many of which had been done elsewhere; in only 2 cases was the patient left with a suprapubic fistula, and there were no deaths. It can therefore be said that since the adoption of penicillin there was a decrease in the number of cystostomies done (10·9% as opposed to 36·9%). Further, a permanent

paper the hæmopoietic responses to folic acid and to the combined liver and iron therapy are compared in cases of nutritional macrocytic anæmia.

LIVER AND IRON

The response of 12 cases of nutritional macrocytic anæmia to parenteral liver, 5 c.cm. of either ' Hepatex ' (Evans) or injectio hepatis (*U.S.P.*) intramuscularly on alternate days, and gr. 30 of ferrous sulphate by mouth daily, is shown in table I and fig. 1. All were Indian males below the age of 35 and strict vegetarians. The anæmia was macrocytic and the colour-index greater than 1; 2 had a mean corpuscular Hb concentration of less than 30% and were considered to be iron-deficient also. All had free HCl in the gastric juice; 4 had ankylostomiasis. None gave a history or id stools suggesting sprue. Blood slides for malarial arasites were negative. Though the anæmia was vere in many cases, angina of effort and œdema were bsent. In addition to liver and iron they received 6 ultivitamin tablets daily and were encouraged to take full diet, including liver, meat, fish, poultry, eggs, ilk, and cheese; but only 2 began to eat meat. During ie same period 34 cases of ankylostomiasis without ppreciable anæmia, and many vegetarians without næmia, were seen. The average increase of red cells as 1,000,000 per c.mm. in 20 days; 8 had a mean orpuscular volume greater than 100 c.μ or showed nacrocytes on the stained film when the red-cell count ad risen to 4,000,000 or more per c.mm. Serial reticulocyte counts and bone-marrow studies were not done n these cases.

ABLE II—EFFECT OF FOLIC ACID ON PERIPHERAL BLOOD IN NUTRITIONAL MACROCYTIC ANÆMIA

ase No.	Red cells (mill. per c.mm.)			Hæmoglobin (g. per 100 c.cm.)			Reticulocytes (%)

13	1·8	1·8	3·8	6·3	6·5	11·9	0·5	0·5	30	5
14	1·7	1·2	3·5	5·6	4·2	10·5	1·0	1·5	32	5
15	1·3	1·4	3·9	4·2	4·2	10·5	2·0	2·0	20	5

FOLIC ACID

Three cases of severe nutritional macrocytic anæmia were treated with synthetic folic acid by mouth, at irst 25 mg., later 15 mg., and finally 5 mg. daily; the ablets were suspended in water as directed by Spies (1946). None of the patients had ever eaten eggs or meat of any sort; their diet consisted largely of rice, vegetable curries, dhal, and chupatties; milk was taken in tea. The red cells were less than 2,000,000 per c.mm. and macrocytic; the colour-index was greater than 1. The bone-marrow contained non-hæmoglobinised megaloblasts and showed typical erythroblastic arrest. No treatment had been given before admission to hospital. During the period of observation the diet was strictly controlled to their usual habits, and folic acid was the sole therapy given.

All 3 patients had smooth tongues, which were not sore, and 2 had crazy-paving roughness of the skin; the nails were normal. Jaundice was absent, and the Van den Bergh reactions were negative. The HCl content of the stomach was normal. Neurological complications and clinical evidence of other vitamin deficiencies were absent. Kahn tests were negative, and malarial parasites were not seen. In 2 cases there was also present ankylostomiasis, with occult blood in the stools. None had chronic diarrhœa or fatty stools. All had lost weight, strength, and appetite, and 2 had fever up to 101°F. Venous congestion, œdema, and angina of effort were absent, though all gave a history of breathlessness on exertion. The results are summarised in table II and illustrated in figs. 2, 3, and 4. In every case a reticulocyte crisis, maximal on the 5th day, was followed by a rapid, steady, and maintained rise in the amount of red cells and Hb, and the marrow resumed a normoblastic pattern. At the same time there was a well-marked increase of weight, strength, and appetite, new papillæ appeared on the tongue, and the skin lost its roughness. In the 2 cases with fever the fall of temperature coincided with the reticulocyte crisis.

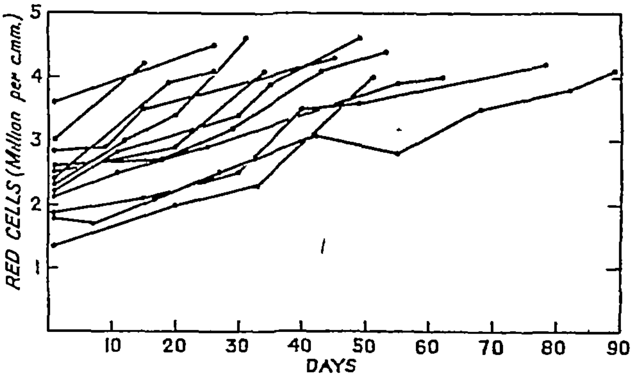

Fig. 1—Increase of red cells in 12 cases of nutritional macrocytic anæmia treated with liver and iron.

Case 13.—A sepoy, aged 22, a life-long vegetarian, had had malignant tertian malaria and smallpox 6 years previously, but no other illness. For 2 months he had noted tiredness, breathlessness on exertion, loss of weight and appetite, occasional vomiting, and feverishness.

On admission he had irregular fever up to 101°F and was pale, with clean tongue, smooth at the margins but not sore. Skin inelastic, with crazy-paving roughness most marked over the back, buttocks, and legs. Systematic examination was negative. Urine normal. Stools contained ova of hookworm and occult blood.

Blood-count: Hb 6·3 g. per 100 c.cm., red cells 1,800,000 per c.mm., mean corpuscular volume (M.C.V.) 116 c.μ, mean corpuscular Hb concentration (M.C.H.C.) 30%, reticulocytes 0·5%. Macrocytes with considerable variation in size were seen on the stained film. White cells 4500 per c.mm. (polymorphs 36%, lymphocytes 56%, eosinophils 8%). Myelograms showing the percentage of nucleated cells on a count of 800 before and after folic-acid treatment are shown in table III.

After a control period of 5 days, during which time there was no improvement, folic acid was given by mouth; the dose and response in the peripheral blood are illustrated in fig. 2.

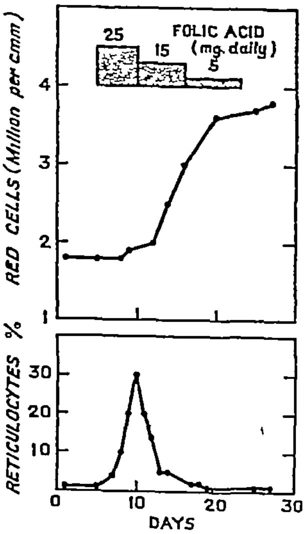

Fig. 2—Effect of folic acid on peripheral blood in nutritional macrocytic anæmia (case 13).

On the 9th day of treatment the marrow had resumed a normoblastic pattern; on the 11th day papillæ could be seen along the margins of the tongue, and the skin had lost its roughness. Weight, strength, and appetite increased.

On the 22nd day the peripheral blood showed Hb 11·9 g. per 100 c.cm., red cells 3,800,000 per c.mm., M.C.V. 113 c.μ, M.C.H.C. 26%. Macrocytes were still present on the stained means to test renal function and to exclude associated urinary lesions and bone metastases from carcinoma. If carcinoma is suspected, the acid serum phosphatase is estimated and stilbœstrol given as a diagnostic measure. Cystoscopy is done about the third day (usually under 'Pentothal') when the final decision to remove or resect is made. The operation is done ten to fourteen days after the acute retention, but the patient must have been absolutely afebrile for a week. Patients are allowed up in twenty-four to forty-eight hours, and the catheter is removed next day, when the penicillin is discontinued, unless the temperature is raised.

Cases without acute retention are similarly investigated and appropriate operation decided, the cystoscopy being deferred to the time of the operation, when it is necessary to be prepared to revise the decision to resect or remove. From the morning of the operation penicillin 20,000 units is given four-hourly for two days and afterwards six-hourly until the removal of the catheter.† No drainage of any residual urine of chronic retention is attempted before operation unless infection is present, but the usual careful attention is given to the heart, lungs, &c.

If biopsy shows carcinoma, subcapsular orchidectomy, as recommended by Hey (1945), is carried out in the hope of lowering the stilbœstrol dosage and delaying the onset of resistance to stilbœstrol; this does not delay the convalescence.

The prostatectomy usually performed is the retropubic, with a transverse incision in the prostatic capsule, which is later sewn up longitudinally; this allows a small tube (equal to no. 20 French catheter) to be placed through the upper end into the bladder for twelve to twenty-four hours (*in addition to the usual catheter*). It affords a valuable alternative route for the drainage if the catheter slips, blocks, kinks, or for any other reason does not work. This is retained for so short a time and is so small that no leak follows its removal. Great attention is paid to excising the V from the prostatovesical ledge to prevent postoperative obstruction, but this allows some oozing from the cavity to escape into the bladder and is another reason for the small bladder tube.

Preliminary suprapubic cystostomy is avoided now and is only rarely used when attempts to pass a catheter have failed in acute retention.

SUMMARY

The value of penicillin as a prophylactic against infection in prostatic surgery has been investigated.

Since penicillin has been given as a routine before and after operation there has been a reduction in the total mortality from 11·3% to 3·1% in all cases of simple enlargement, and after prostatectomy (removal or resection) from 5% to 2·6%. Before the introduction of penicillin 36·9% of all cases were submitted to cystostomy with a case-mortality of 15%; since penicillin has been used the proportion has been reduced to 10·9% with no mortality.

Penicillin is recommended for any period of indwelling catheter in prostatic surgery, and dosage is suggested.

A broad outline for the management of prostatic patients is given.

My thanks are due to Dr. E. ff. Creed, of the pathological department, King's College Hospital, and to Dr. David Nabarro, lately in charge of the pathological department, Emergency Hospital, Leatherhead, for their help in the penicillin investigations; and to Mr. W. Waugh for preparing the statistics and for his skilful care of the patients as house-surgeon and surgical registrar at King's College Hospital.

LIVER AND FOLIC ACID IN THE TREATMENT OF NUTRITIONAL MACROCYTIC ANÆMIA

A COMPARISON OF RESULTS

T. A. KEMP
M.B. Camb., M.R.C.P.
LIEUT.-COLONEL, R.A.M.C.

NUTRITIONAL macrocytic anæmia is a deficiency anæmia, often severe, most commonly seen in vegetarians, and aggravated by pregnancy. The anæmia is macrocytic, and the bone-marrow shows megaloblastic hyperplasia. Crude liver extracts, autolysed yeast, and synthetic folic acid are curative. Ankylostomiasis, sprue, malaria, and syphilis are often also present. Though the peripheral blood picture is very similar to that of Addisonian pernicious anæmia, hæmolytic jaundice, achlorhydria, and subacute combined degeneration of the cord do not develop, and sore tongue is rare. The age-incidence is younger, 20–35, and refined liver extracts given parenterally are without effect. These clinical observations have led to the idea that the response of nutritional macrocytic anæmia to crude liver extracts or to autolysed yeast is due to some other substance than pure liver principle or extrinsic factor.

Before the synthesis of folic acid (*Lactobacillus casei* factor present in liver) by the team of investigators at the Lederle laboratories (Angier et al. 1945), and the clear demonstration by Spies et al. (1945) that it was effective in many types of macrocytic anæmia associated with megaloblastic hyperplasia of the bone-marrow, including Addisonian anæmia, nutritional anæmia, pregnancy, sprue, and pellagra, it was customary to treat nutritional macrocytic anæmia with crude liver extracts and iron. Trowell (1943) showed that in Africa the deficiency was often dual, and he coined the term dimorphic anæmia. However, the hæmopoietic response was often strikingly slow compared with that of Addisonian anæmia, and the amount of liver required was very much greater. The discovery of folic acid has opened a new era in the treatment of macrocytic anæmia, and it is of the utmost importance that a full clinical assessment of its value and limitations be made so that it is not squandered on unsuitable cases without adequate control, as so often happens with new and potent remedies. In this

TABLE I—NUTRITIONAL MACROCYTIC ANÆMIA TREATED WITH LIVER AND IRON

Case no.	Before treatment		After treatment	
	Red cells (mill. per c.mm.)	Hb (g. per 100 c.cm.)	Red cells (mill. per c.mm.)	Hb (g. per 100 c.cm.)
1*	1·8	5·6	4·2	12·8

* Iron-deficient. † Ankylostomiasis.

time there was an increase of weight, strength, and appetite; new papillæ appeared on the tongue, and the crazy-paving roughness of the skin present in 2 cases disappeared. Since the diet was controlled and folic acid was the sole therapy given, it seems likely that the dramatic hæmopoietic response and clinical improvement were due to folic acid.

The peripheral blood returned to normal at a much more rapid rate than had previously been observed with large doses of liver parenterally and iron by mouth; the red cells increasing at the rate of 1,000,000 per c.mm. in 5 days, as compared with 1,000,000 per c.mm. in 20 days.

From a study of these cases it appears that folic acid alone by mouth is a more powerful remedy in the treatment of nutritional macrocytic anæmia than are crude liver extracts given parenterally and supplemented by iron by mouth; and it is hoped that this report will stimulate further trials in Asiatic countries.

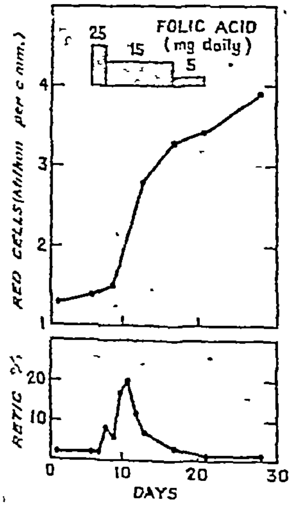

Fig. 4—Effect of folic acid in case 15.

SUMMARY

In 3 cases of nutritional macrocytic anæmia with megaloblastic hyperplasia of the bone-marrow folic acid produced a more rapid improvement in the peripheral blood than would have been expected with large doses of liver extract parenterally and iron by mouth. The bone-marrow resumed a normoblastic pattern.

I am indebted to Lieut.-Colonel W. R. M. Drew, O.B.E., R.A.M.C., professor of medicine in the University of Bagdad, for much helpful advice and criticism; Major A. S. Brown, I.M.S., and Captain S. M. H. Bokhari, I.A.M.C., for their clinical assistance; and Major R. Fleming, I.M.S., for the laboratory investigations.

". . . In the first flush of enthusiasm for the industrial revolution that resulted from the practical applications of science, it was felt that the consequences of such application could only be for the good of man. As we have seen more of these consequences, however, and thought more deeply on such matters, we now realise that the practical results of science will be good or evil, in the ethical sense, depending on the nature of the application. . . . The evils that can result from wicked application do not mean that science itself is evil. Each pure science merely gives an objective account of the facts which it finds in its own field of study. These facts are ethically neutral; it is only their application that can lead to evil rather than good results. Moreover, from a broader and deeper point of view, the pursuit of these ethically neutral facts must itself be regarded as a good. It is a spiritual good, since knowledge of the true nature of the world in which he lives should increase the intellectual dignity of man. It is a practical good, since it is only through knowledge of the actual facts that men of good will can plan for their application to good rather than evil ends. Keeping certain facts secret, as in the field of atomic energy, can be temporarily important and serve a useful purpose, but can make no fundamental contribution to the prevention of evil."—RICHARD C. TOLMAN. *Science*, Aug. 15, 1947, p. 140.

ACUTE ANTERIOR POLIOMYELITIS COMPLICATING PREGNANCY

D. M. W. MAXWELL
M.B. Edin., F.R.C.S.E., M.R.C.O.G.
OBSTETRICIAN AND GYNÆCOLOGIST

PHILIP H. WILLCOX
M.A., M.D. Camb., M.R.C.P.
ASSISTANT PHYSICIAN

KING EDWARD VII HOSPITAL, WINDSOR

POLIOMYELITIS is relatively uncommon in adults, and the chances of its coinciding with pregnancy are therefore very small. No cases of such coincidence have so far been published in this country. In the United States, on the other hand, where the number of cases of the disease is much greater, the subject of poliomyelitis in pregnancy has often been discussed in the medical press. In view of the present outbreak here the following record may be of interest to obstetricians and others who may find themselves called on to deal with the condition.

THE CASE

On Nov. 27, 1946, one of us (P. H. W.) was called into consultation to see a woman, aged 32, in her home, with a history of malaise and rise of temperature to 99·6°F on Nov. 22, accompanied by aching pains between the shoulders. On Nov. 24 there had been severe pain in the lumbar region and nausea; temperature 100·6°F. Patient had noted that on trying to get out of bed her arms and legs were weak. On Nov. 26 she had vomited and had had difficulty in leaning to the side of her bed; and she also had dysphagia with palatal paralysis.

Examination (Nov. 27).—Complete paralysis of left lower limb, no spontaneous movements being possible. Right lower limb less severely affected, but quadriceps femoris and dorsiflexors of foot powerless. Contraction of flexors of foot and knee very weak. Paresis of both arms, the triceps on either side being most affected, and the flexors of wrists and elbows less so. Complete deltoid paralysis on right side. Rectus abdominalis and other trunk muscles also affected, but no alteration in depth or rate of respiration.

Biceps and supinator reflexes brisk on both sides; triceps-jerks elicited. Ankle-jerks brisk on both sides, but knee-jerks absent. Plantar responses doubtful. Some hyperæsthesia of dorsum of feet and of legs, but no sensory loss.

Cranial nerves showed no abnormal physical signs; fundi normal. Temperature 99·4°F, respirations 20 per min. Urine: no albumin, sugar, or acetone. Heart, lungs, and ear, nose, and throat normal. Uterus enlarged as for a 26-week pregnancy.

Acute poliomyelitis was diagnosed and patient admitted to hospital, where the cerebrospinal-fluid findings were: pressure 160 mm. water; clear fluid; 10 lymphocytes per c.mm.; protein 50 mg., chlorides 692, sugar 57 mg./100 ml.; globulin, weakly positive Pandy reaction.

A white-cell count showed 7600 per c.mm. (polymorphonuclears 71%, lymphocytes 24%, hyalines 1%).

Course of Illness.—There was subsequently no further rise of temperature above normal while patient was in hospital. Fœtal heart sounds were heard, and movements were felt.

In the light of American experience, it was decided that there was no indication to interfere with the pregnancy, and the paralysis was treated by the usual methods for poliomyelitis. From Nov. 29 to Dec. 1 there was retention of urine, necessitating catheterisation. Bowels inactive; enemas had to be given regularly for several weeks.

By Dec. 7 considerable improvement had taken place: urine was passed naturally, and movement of all leg muscles on both sides was possible though weak; deltoid paralysis had diminished, and power in arms, particularly the left, showed a surprising degree of recovery.

By the end of January all arm movements were possible and legs showed considerable recovery of power; but patient still could not sit up in bed, the abdominal muscles were feeble, and it was clear that during pregnancy she would never recover sufficiently to stand or walk.

Obstetric History.—Married 7 years. First child aged 6, born June 31, 1940; normal labour at 42 weeks; birth-weight 9 1/2 lb. Second child, aged 4 1/2 born Feb. 25, 1942;

TABLE III—MYELOGRAMS BEFORE AND AFTER FOLIC-ACID THERAPY IN CASE 13

—	Percentage of nucleated cells	
	Before folic acid started	*9th day of treatment*
Total nucleated cells	47,000/c.mm.	142,000/c.mm.
Myeloid series/nucleated reds	2 16/1	1·56/1
Megaloblasts	9*	1·5
Early erythroblasts	6	5
Late erythroblasts	3†	3
Normoblasts	10	28·5
Myeloblasts	3·5	0·5
Premyelocytes	5	1·5
Myelocytes	8	7
Metamyelocytes	8	5
Polymorphs	38	45·5
Lymphocytes	9	2
Monocytes	0·5	0·5
Plasma cells	—	—
Unclassified cells	—	—
Parasites	—	—

* A few mitotic figures were seen.

† Hæmoglobinisation did not start earlier than the late erythroblasts.

film. White cells 9200 per c.mm. (polymorphs 52%, lymphocytes 33%, monocytes 6%, eosinophils 9%). Patient had gained 9 lb. in weight.

No anthelmintics were given during the period of observation. The reticulocyte crisis and subsequent increase of red cells, 1,000,000 per c.mm. in 5 days, fully satisfy the *U.S.P.* standard.

Case 14.—A sepoy, aged 34, a life-long vegetarian, had had an untreated penile sore 6 years earlier, and bacillary dysentery 2 years earlier, but no other past illness. For 2 months he had noted increasing lassitude, breathlessness on exertion, and anorexia. Stools had been occasionally loose but never fatty or offensive. He had lost weight.

On admission he had no fever but was pale, with clean smooth tongue and crazy-paving roughness of legs. Penile scar. *Heart, lungs, and abdomen normal. Ankle-jerks* absent; other tendon-jerks very sluggish. Central nervous system otherwise normal. Kahn test negative. Cerebrospinal fluid normal in all respects. Urine normal. Stools negative.

Blood-count: Hb 5·6 g. per 100 c.cm. Red cells 1,700,000 per c.mm., M.C.V. 123 c.μ, M.C.H.C. 27%, reticulocytes 1%. Macrocytes and a few *normoblasts were seen on the stained* film. White cells 5500 per c.mm. (polymorphs 49%, lymphocytes 45%, monocytes 5%, eosinophils 1%). The bone-marrow showed non-hæmoglobinised megaloblasts with erythroblastic arrest.

TABLE IV—MYELOGRAMS BEFORE AND AFTER FOLIC-ACID THERAPY IN CASE 15

—	Percentage of nucleated cells	
	Before folic acid started	17th day of treatment
Total nucleated cells	70,000 /c.mm.	90,000 /c.mm.
Myeloid series/nucleated reds	0·72/1	1·3/1
Megaloblasts	15*	1·5
Early erythroblasts	16	4·5
Late erythroblasts	11†	10
Normoblasts	12	21
Myeloblasts	2	0·5
Promyelocytes	2	0 5
Myelocytes	3	3
Metamyelocytes	4	4·5
Polymorphs	28	45
Lymphocytes	4	5 5
Monocytes	2	1
Plasma cells	—	—
Unclassified cells	1	—
Parasites	—	—

* Many mitotic figures were seen.

† Hæmoglobinisation did not start earlier than the late erythroblasts.

During the control period of 9 days the amount of red cells fell to 1,200,000 per c.mm. and of Hb to 4·2 g. per 100 c.cm. The dose of folic acid and the response in the peripheral blood are illustrated in fig. 3.

On the 22nd day of treatment the *peripheral blood* showed Hb 10·5 g. per 100 c.cm., red cells 3,500,000 per c.mm., M.C.V. 98 c.μ, M.C.H.C. 30%. A few macrocytes were seen on the stained film. White cells 5300 per c.mm. (polymorphs 66%, lymphocytes 28%, monocytes 2%, eosinophils 4%), and the bone-marrow was of normoblastic type. New papillæ were growing on the tongue, and the skin was normal. Weight, strength, and appetite had increased. Ankle-jerks remained absent.

The reticulocyte crisis and subsequent increase of red cells, 1,000,000 per c.mm. in 5 days, fully satisfy the *U.S.P.* standard.

Case 15.—A havildar clerk, aged 25, a life-long vegetarian. An undiagnosed fever 5 years previously was the only past illness. For 1 month he had noted increasing weakness, breathlessness on exertion, loss of weight and appetite, vomiting, and feverishness.

On admission he had irregular fever up to 101°F and was very pale with clean tongue, without papillæ at the margins but not sore. *Skin and nails normal. Systematic* examination negative. Urine normal. Stools contained ova of hookworm and occult blood.

Blood-count: Hb 4·2 g. per 100 c.cm., red cells 1,300,000 per c.mm., M.C.V. 123 c.μ, M.C.H.C. 26%, reticulocytes 2%. Normoblasts, macrocytes, and considerable variation in size, shape, and staining were present on the stained film. White cells 5600 per c.mm. (polymorphs 55%, lymphocytes 36%, monocytes 3%; eosinophils 6%). Myelograms showing the percentage of nucleated cells on a count of 800 before and after folic acid treatment are shown in table IV.

During the control period of 6 days there was a slight increase of red cells to 1,400,000 per c.mm., but the amount of Hb remained unchanged. The dose of folic acid and the response in the peripheral blood are illustrated in fig. 4.

On the 17th day of treatment the bone-marrow had resumed normoblastic pattern, and papillæ were growing along the *margins* of the tongue.

On the 22nd day the peripheral blood showed Hb 10·5 g. per 100 c.cm., red cells 3,900,000 per c.mm., M.C.V. 91 c.μ, M.C.H.C. 28%. A few macrocytes were still present on the stained film. White cells 4600 per c.mm. (polymorphs 49%, lymphocytes 35%, monocytes 6%, eosinophils 10%). The appetite was normal. Patient had gained 10 lb. in weight.

No anthelmintics were given during the period of observation. The reticulocyte crisis and subsequent increase of red cells, 1,000,000 per c.mm. in 5 days, fully satisfy the *U.S.P.* standard.

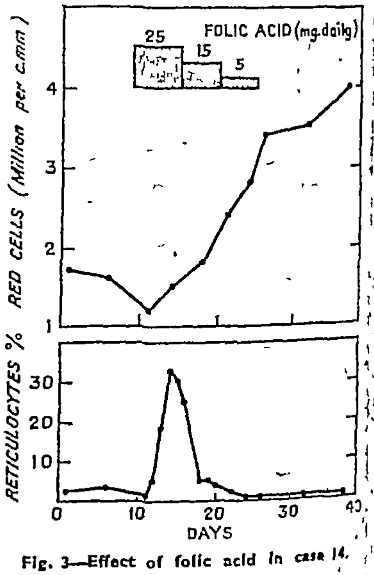

Fig. 3—Effect of folic acid in case 14.

DISCUSSION

After a control period synthetic folic acid was given by mouth in 3 cases of *nutritional macrocytic anæmia*. In every case a maximal reticulocyte response, average 27%, took place on the 5th day and was followed by a steady increase of red cells and Hb towards normal, 1,000,000 per c.mm. *and* 2 g. per 100 c.cm. respectively in 5 days during the most rapid period of recovery. The bone-marrow showed a great reduction of megaloblasts and an increase of normoblasts. At the same wer; nor did the disease affect the expulsive power the uterine muscle.

These findings are in accordance with American perience in similar cases. There is no evidence that e fœtus can be infected before delivery. The only ses on record in which fœtal death took place before livery have been due to asphyxiation secondary to spiratory paralysis in the mother.

There is evidence that the newborn child has antidies which protect it from infection in the first few eks of life. A few cases of poliomyelitis in the first onth are, however, on record.

On these grounds there is no evidence that interence with pregnancy or cæsarean section is ever dicated in cases of poliomyelitis in pregnant women, cept for circumstances which would equally apply all pregnant women.

It is hoped that other cases may be reported to substantiate or refute any observations made in this case d those recorded in the American literature.

We wish to thank Dr. H. M. Jaques, of Burnham, Bucks, kindly permitting us to treat the case and to publish this record; Mr. G. P. Arden, for his valued advice and re of the patient; and the nurses and physiotherapy partment at King Edward VII Hospital, Windsor.

ACUTE AMŒBIASIS COMPLICATING CHOLECYSTECTOMY

REPORT OF A CASE

K. M. ROBERTSON
M.D. Lond., F.R.C.P.
HYSICIAN, ROYAL HANTS COUNTY HOSPITAL, WINCHESTER, AND ROYAL SOUTH HANTS HOSPITAL, SOUTHAMPTON

THE following case is reported as there must be many tients with latent amœbiasis brought back from the opics who will be subjected to abdominal and other rgical operations.

In September, 1946, a man of 37, who had spent a large rt of the last twenty years in Northern Rhodesia, was dmitted for cholecystectomy for calculi. Operation had been dvised, in spite of the absence of symptoms, in view of his tended early return to Rhodesia.

The patient's previous history included a severe attack of ackwater fever in Birmingham, two months after his urn from Africa in 1933. Though his life was threatened, had made an excellent recovery, apart from an acute pendicitis which had complicated his convalescence. This d been dealt with surgically, and after a few years in this untry he had been allowed to return to Rhodesia in 1937.

Since the operation for appendicitis his health had been xcellent. He was not aware of having had any dysenteric fection, but for years he had from time to time had short tacks of diarrhœa. These had rarely lasted more than a y but had been associated with tenesmus and had often rminated in "an attack of piles." He had never received tidysenteric treatment.

Operation (Mr. William Everett).—The patient was anæsthetised with 'Pentothal,' curare, and gas and oxygen. Kocher's incision was used. The gall-bladder was full of all pigment stones and bili ry sand, thought to be a legacy fundus of the gall-bladder was buried for about an inch in liver substance, and its removal demanded a small incision into hepatic tissue. The small cavity thus produced was carbolised before being closed. The liver and all the colon which could be seen appeared to be healthy and normal.

Postoperative Course.—The immediate postoperative period was uneventful, and by the third day the patient felt very well and had been out of bed several times. On the evening of that day he received a routine aperient. Next morning it appeared that this dose had been excessive, for he had several loose stools and was uncomfortable. By the evening, with symptoms persisting in spite of symptomatic treatment, his temperature rose to 100°F. From this point his condition deteriorated, bowel action became more frequent and urgent, the temperature rose higher, and there was considerable abdominal pain. Early in this illness several motions were examined for evidence of infection, and, though amœbiasis had not been suspected, the examination included a fruitless search for amœbæ and cysts. The white-cell count was moderately increased to 14,000 per c.mm., with a relative increase in polymorphs. Repeated search for evidence of malaria proved negative.

By the twelfth postoperative day his conjunctivæ were icteric and the Van den Bergh test gave a direct positive result. The patient was now very ill, with a tender distended abdomen and signs of ascites. The diarrhœa continued intermittently in spite of succinyl sulphathiazole in full doses. Evidence of subphrenic or pelvic suppuration was looked for but none was discovered, though rectal examination was painful and to the examining finger the rectal wall seemed to be much indurated.

Re-exploration of Abdomen.—This was carried out through the original wound. When the peritoneal cavity was entered, much thin bloodstained fluid escaped. The operation site was satisfactory, and a hand passed above the liver and into the pelvis confirmed the absence of suppuration in either of these situations. The whole of the colon which was accessible was intensely inflamed, with gross thickening of the gut wall and induration of the pericolic tissues, especially in the ascending colon and hepatic flexure, where the inflammation was severe enough to suggest the possibility of abscess formation in the right renal gutter. During the exploration of this region the gut was torn by the finger and the bowel contents, pale and granular from the ingested succinyl sulphathiazole, escaped freely. By this time the possibility of amœbic colitis had suggested itself, and a sample of the escaping fæces was rapidly examined microscopically. Typical vegetative forms of *Entamœba histolytica* were present in very large numbers, motile, and showing ingested red cells. A wide-bore tube was stitched into the gut, free drainage of the abdominal cavity was instituted, and the wound was closed with steel wire. The patient, who had been on the table for nearly three hours, was immediately given a transfusion of three pints of blood, followed by glucose and glucose-saline maintained for four days, during which nothing was given by mouth.

Emetine gr. 1 was given twelve-hourly for three doses, and subsequently daily, until a total of gr. 12 had been given, and penicillin 100,000 units was injected three-hourly for a week. During most of this week the patient's condition was desperate. His temperature remained high, his pulse-rate rose to 140 per min., and the jaundice deepened until an icteric index of 60 was reached. As soon as fluid was allowed by mouth, succinyl sulphathiazole 8 g. eight-hourly was given. Towards the end of the week clinical improvement was manifest, and from this point there was, on the whole, steady and maintained advance towards a recovery, which now appears to be complete.

After the course of emetine injections, emetine bismuth iodide was administered, and later still a course of carbarsone was instituted. No local treatment to the bowel was undertaken. The patient left the nursing-home at the end of eight weeks, well but with a small fæcal fistula which has since healed, and a recent full examination has not revealed any evidence of residual dysenteric infection.

COMMENTS

In this case a "cold" cholecystectomy seems to have caused an unsuspected amœbiasis to flare up. Possible factors influencing this complication include trauma to big bowel from retractor pressure, and the incision into the liver and subsequent carbolisation of the small hepatic cavity. A general lowering of resistance as a result of normal labour at 41½ weeks; birth-weight 10½ lb. One miscarriage at 3 months on Dec. 6, 1945. Menses regular 4–5/28. Last menstrual period May 23, 1946. Expected date March 2, 1947.

The patient was seen first at 28th week of pregnancy, when paralysis was very well marked. The uterus was slightly small for the dates. The urine contained no albumin or sugar. Blood-pressure 118/68. She was examined throughout rest of pregnancy at intervals of two or three weeks. There was no evidence of toxæmia, nor any abnormality detected except the paralysis, which gradually improved. Blood-count (Feb. 17, 1947): red cells 3,400,000 per c.mm.; Hb 75%.

On March 8, as she was a few days overdue according to her dates, castor oil and an enema were administered. Pains started between 4 and 5 P.M. on same day, and the progress of labour was watched continuously from 9 P.M. until 1.30 A.M. on the 9th. Dilatation of os was very slow, though position of baby was anterior and presentation a vertex. At 1.30 A.M. on the 9th, pethidine 100 mg. was given; this was repeated two hours later. At 6.30 A.M. patient appeared to be fully dilated, and head had descended to pelvic floor, but at that stage patient could not help herself any further and she indicated that she could not bear down or express the child's head as she had done with the previous two children. General anæsthesia was then given, small-outlet forceps were applied, and a living female child weighing 9 lb. 4 oz. was delivered at 9.15 A.M. The placenta separated about 20 minutes later and was expressed from the vagina.

The patient's conditions was eminently satisfactory afterwards, with no fever, and she nursed the baby entirely on the breast.

Subsequent Progress.—The child did well and was healthy in every way; no sign of paralysis or weakness; weight 15½ lb. at 4 months of age. Pregnancy and childbirth had no adverse effect on progress of the mother towards recovery of power. On July 10 she could walk with the aid of a stick and a plaster support to the right knee. She said she was getting stronger day by day, though the right quadriceps muscle and the muscles of the back were weak.

DISCUSSION

If it is true, as suggested by Aycock (1941), that pregnant women are more susceptible than non-pregnant women to the virus, poliomyelitis will always be likely to arise in pregnancy, and knowledge of the subject is essential for practising obstetricians and physicians from whom advice may at any time be sought.

Incidence of Poliomyelitis in Pregnancy

Weaver and Steiner (1944) collected records of 75 cases between 1906 and 1943 of which 61 had been reported since 1930, representing an average of almost 5 yearly in the United States. Probably only a small fraction are recorded. Kleinberg and Horwitz (1941) were able to describe 13 unpublished cases which had been under the care of colleagues, and Brahdy and Lenarsky (1933) personally observed 3 cases within a year.

Aycock (1941), estimated the probability of poliomyelitis and pregnancy coinciding at less than 1 in 1000 cases of poliomyelitis and less than 1 in 50,000 pregnancies.

Susceptibility in Pregnancy.—The idea that the hormonal changes of pregnancy, make women particularly susceptible to the virus is supported by animal experiment (Jungeblut and Engle 1934, Aycock 1937, 1940). Aycock (1937) showed that injection of œstrogenic substances into castrated immature female monkeys enhanced their resistance to intranasal instillation of virus. Comparative urinary œstrogen assays showed higher excretion of these substances in poliomyelitis patients than in controls (Aycock 1940).

Weaver and Steiner (1944), among others, have noted that the incidence of poliomyelitis in pregnancy varies according to the stage of pregnancy, and recorded in 70 cases the following incidence:

1st	third	of	pregnancy	17·1 %
2nd	,,	,,	,,	34·3 %
3rd	,,	,,	,,	48·6 %

In experiments in pregnant cotton-rats they demonstrated that of 13 animals in the first third of pregnancy 3 were resistant to the virus, whereas 51 animals in later pregnancy all developed the disease after three-way inoculation of virus (intracerebral, intranasal, and subcutaneous).

Most writers consider that poliomyelitis has no adverse effect on pregnancy or labour (Brahdy and Lenarsky 1933, Kleinberg and Horwitz 1941). The exceptions to this rule when applied to pregnancy are to be found in cases of widespread paralysis in the mother, in which case death of the fœtus in utero from asphyxia is the obvious risk (Harmon and Hoyne 1943). Aycock and Ingalls (1946) have collected records of the fate of the fœtus in 131 cases: in 25 cases the baby was stillborn or died shortly after birth; and in 6 cases abortion occurred in the first three months.

That the uterus has an independent nerve-supply is shown by the fact that normal contraction occurs after transection of the spinal cord or after experimental division of the sympathetic nerve-supply (Wright 1940). Moreover the ability of the uterus to expel its contents has been observed also in cases of cord tumour and fracture with cord involvement. In 243 cases pregnancy has taken place within a year of the onset of poliomyelitis; normal and uneventful pregnancies and labours were experienced in all cases (Kleinberg and Horwitz 1941).

There is therefore strong evidence that pregnancy and labour should not be interfered with except for complications operative for all pregnant women. While both termination of pregnancy and cæsarean section have been done in these cases, from clinical experience there is no evidence that they were indicated on reasonable grounds.

Infection of the Child

No authentic instances of transmission of the virus of poliomyelitis from the mother to the offspring in utero are on record. Unlike the virus of vaccinia encephalitis, measles, chickenpox, and variola, which may be found in the bloodstream, the virus of poliomyelitis is rarely recoverable from the circulating blood of patients, or at any rate is never present in sufficient amount to pass through the placental circulation (*Journal of the American Medical Association* 1943).

Poliomyelitis may occur in infants in their first month but is rare under the age of 6 months. Biermann and Piszczek (1944) described a case in a newborn infant which developed symptoms on the 11th day after delivery and paralysis of the lower extremities on the 13th day; the mother developed symptoms on the 1st day after delivery and died on the 4th day. In this case infection may have taken place either during exposure at birth or during the short period of ten minutes when the infant was placed for the only time in close proximity to the mother after birth.

That infection may occur at delivery from fæcal contamination is highly likely in view of the fact that the virus of poliomyelitis is known to exist in the stools in the early stages of the disease (Paul and Trask 1941, Howe and Bodian 1940). The infrequency of the disease in the first month of the infant's life is probably due to the relative unlikelihood of the mother's acquiring the disease at or near full term; but, as suggested by Aycock and Kramer (1930) and by Shaughnessy et al. (1930), it is also due to the fact that the infant has antibodies which persist several months after birth. Weaver and Steiner (1944) consider that there is no evidence that passage of the virus from mother to infant through the milk can take place. Experimentally they showed that 2 mother cotton-rats infected 24 hours after delivery did not convey the infection to their 8 offspring, who fed from their mothers from birth until the mothers died on the 8th and 11th days.

SUMMARY

A case is described in which acute anterior poliomyelitis occurred in the 6th month of pregnancy. The patient was treated conservatively and allowed to proceed to full term; a normal healthy female child weighing 9 lb. 4 oz. was successfully delivered. No complications occurred, except that there was delay at the pelvic floor and the child was delivered with forceps. Pregnancy and labour had no adverse effect on the gradual progress of the patient towards recovery of

SUPERFICIAL PHLEBITIS

Ambulatory Treatment With Elastoplast Bandaging

CASE HISTORY—L. L. Aged 42. A female Sugar Packer. Whilst at work on *June 16th*, 1946, she cut the outer side of her left ankle; shortly afterwards a septic eczema of the ankle area supervened. On *July 26th*, a large clot appeared in the internal saphenous vein on the inner side of the calf (Fig. 1).

TREATMENT. *August 9th*, 1946. A well-bevelled adhesive sponge rubber pad was placed over the clot, the eczema was covered by layers of 'Viscopaste' and the leg firmly bandaged with 'Elastoplast' from toes to knee (Fig. 2). *August 23rd*, 1946. There was no pain or soreness in contrast to the presence of both before treatment. Eczema was cleaned with calamine in oil, and dressed with 'Jelonet' and 'Ichthopaste.' The pressure pad was re-applied and the leg again firmly bandaged with 'Elastoplast.'

August 30th, 1946. Treatment repeated. *Sept. 27th*, 1946. Clot completely disappeared, leg comfortable, eczema largely cleared up and internal saphenous vein sclerosed and obliterated (Fig. 3).

COMMENT. An example of ambulatory treatment of Phlebitis by local pressure over clot and firm bandaging, resulting in its speedy obliteration and in the restoration of the leg to normal condition. Details and illustrations above are of an actual case. T. J. Smith and Nephew Ltd., Manufacturers of 'Elastoplast,' 'Viscopaste,' 'Jelonet' and 'Ichthopaste,' are privileged to publish this instance, typical of many, in which their products have been used with success, in the belief that such authentic records will be of general interest.

ELASTOPLAST elastic adhesive bandages are available in widths of 2", 2½", 3" and 4" × 5/6 yds. long when stretched. Also in 2" wide × 1¾ yds. long (stretched).

ICHTHOPASTE bandages are of the Unna's Paste type but contain 5% Ichthyol. The bandages are 3½" wide × 6 and 10 yds. long.

JELONET (TULLE GRAS) is an open mesh gauze dressing impregnated with petroleum jelly and 1% Balsam of Peru. It is indicated as a dressing for skin grafts and in the treatment of wounds, burns, etc. Jelonet is sterilised ready for use and is supplied in 8 yd. continuous strips or in cut pieces 3¾" × 3¾".

ELASTOPLAST, JELONET AND ICHTHOPASTE *are products of* T. J. SMITH & NEPHEW LTD., HULL surgery probably played a considerable part, and it must be recalled that acute malaria sometimes follows surgery in cases harbouring this infection. Whatever the causal factors which were at work in this case it is clear that any or all of them might well operate in any abdominal surgical operation.

I wish to thank Prof. Hamilton Fairley for advice on the treatment of the amœbiasis and Mr. Lawrence Abel for invaluable surgical help. To the late Mr. William Everett, upon whose shoulders rested the heavy anxiety of this desperate case, my especial gratitude is due.

Reviews of Books

The Louse

(2nd ed.) P. A. BUXTON, C.M.G., F.R.S., director, department of medical entomology, London School of Hygiene and Tropical Medicine. London: E. Arnold. 1947. Pp. 164. 10*s.* 6*d.*

MOST large textbooks have defects and nearly all have rivals; but it is still possible to find monographs on restricted subjects that stand alone and are completely satisfactory. Professor Buxton's book on the human louse provided the medical parasitologist, the hygiene official, and the entomologist, with all information available up to the outbreak of the recent war. Since then there has been an inevitable spate of research, much of it his own; so this new edition of the book has expanded from 115 to 164 pages, and many sections have been revised. There are interesting new data on field observations of natural populations of head and body lice, on the sensory physiology and behaviour of lice, and on their resistance to heat, cold, and insecticides. The section dealing with man's reaction to louse bites has been amended in the light of further knowledge. Many sources have been tapped, including recent Russian work. The chapter on control of lice has been rewritten. Modern insecticides have profoundly modified the practice of disinfestation, but some of the older remedies are mentioned, because they might be of value in the absence of better materials. Among 47 informative graphs and diagrams is the picture of a modified garter for ladies who volunteer to feed lice. It is worn above the knee, so that they can suffer in secret.

Die Bluteiweisskörper des Menschen

F. WUHRMANN, DR. MED., chief physician to the University Medical Clinic, Zürich; C. WUNDERLY, DR. ING. CHEM., chief scientific assistant at the clinic. Basle: Schwabe. 1947. Pp. 354. Sw. fr. 36.

THIS is a comprehensive well-documented monograph on the chemical and physicochemical properties of the proteins, normal and abnormal, that are found in the blood plasma, and the clinical applications. Specialists have been called in to write some sections: F. Leuthardt deals with the solubilities of plasma proteins, E. Wiedemann contributes a lengthy section on electrophoresis, and R. Signer briefly describes the ultracentrifuge.

The book begins with a concise discussion of present views on the chemistry of proteins. "Albuminuria," it is noted, is not a correct term; the kidney filtrate depends on the size of the particle, and since β-globulin and fibrinogen also pass through, "proteinuria" is more correct. A chapter on methods contains, besides the technical sections on solubility, electrophoresis, and the ultracentrifuge, an account of the qualitative and quantitative methods used in clinical biochemistry for detecting and estimating plasma proteins, including fibrinogen and prothrombin, as well as tests depending on plasma-protein variations—such as blood-sedimentation rate, the thymol turbidity test, the cephalin-cholesterol flocculation test, and the cadmium turbidity test. All these methods are applied to the study of plasma-protein variation in disease.

Eight tests are selected: the E.S.R., a heat-coagulation test (Weltmann's band), the nephelogram, a flocculation test such as the Takata-Ara, the cadmium turbidity, the total serum proteins, the salt (phosphate) solubility curve, and the electrophoretic pattern. By putting the results of all these tests together in a graphic manner on a diagram, six types of "reaction constellation" are obtained with diagnostic differences.

These types are: (1) acute inflammation, including early cardiac infarction; (2) subacute and chronic infections (and this includes early malignancy); (3) the diffuse liver-damage type—fibrotic pulmonary tuberculosis, some cases of polyarthritis, and some cases of lymphatic leukæmia and lymphosarcoma show this reaction type; (4) the nephrotic type found in all cases of lipoid nephrosis, whether "pure" or "nephritic"; (5) the γ-globulin plasmacytoma type, which includes lymphogranuloma inguinale, kala-azar, the so-called reticuloses, and others; (6) the β-globulin plasmacytoma type, into which also come some cases of myeloid and lymphatic leukæmia, subacute and chronic polyarthritis, and metastatic carcinoma.

The authors emphasise that it is only by studying all the tests together that diagnostic information can be obtained, and they give a striking list of conditions in which only uninformative results can be obtained from tests taken singly, or from the E.S.R., Weltmann's band, the Takata-Ara test, and the cadmium turbidity taken together.

They discuss types of disease in which hyperproteinæmia or hypoproteinæmia occur; and they also distinguish "dysproteinæmia," where one or more proteins are affected, but not all—for example, fibrinogenopenia, and "paraproteinæmia" in which abnormal proteins appear (e.g., myelomatosis). The syndromes of "essential" hyperproteinæmia and hypoproteinæmia are described; the latter is interesting because it includes cases described elsewhere as "essential œdema," or "nephrosis without nephrosis." They deal briefly with the formation of plasma proteins, and in the last chapter describe the therapeutic use of protein preparations, including plasma fractions and protein hydrolysates.

Here then is an up-to-date exposition of the subject. Much emphasis is placed on electrophoresis and solubility curves, and the authors are clearly of opinion that unless these methods are used, all the others are not likely to help. These two investigations, however, at present find little place in clinical pathology, and we are not yet convinced that these none-too-simple procedures have earned their place as diagnostic tests. For clinical researches involving protein studies they are, we agree, essential, and all interested in protein disturbances can be recommended to tackle this book.

A Handbook of Psychiatry

LOUIS J. KARNOSH, M.D., SC.D., with the collaboration of EDWARD M. ZUCKER, M.D. London: H. Kimpton 1945. Pp. 302. 25*s.*

WELL illustrated and easy to follow, this textbook gives an unadventurous well-informed account of psychiatric practice. Its authors have written it with an eye to the peculiar needs of the general practitioner and have supposed, perhaps rightly, that he does not want to be warned where psychiatrists are uncertain about their assumptions or told what intricacies cause them to differ about such matters as psycho-analysis. Some of the defects of this approach can be seen in the section on psychoneuroses, which would probably be more often consulted by a general practitioner than any other part of the book, yet fails to tell him as much as he would like to know about the management of hypochondriacal and other common but obstinate problems.

X-Rays and Radium in Diseases of the Skin (4th ed. London: H. Kimpton. 1946. Pp. 668. 50*s.*).—The new edition of this popular textbook by Dr. G. M. MacKee, Dr. A. C. Cipollaro, and Dr. Hamilton Montgomery shows several changes. Much of the material contributed to previous editions has been retained, but the section on physics has been reduced by about a third. This is wise, since all necessary information can be found in any standard textbook on radiation-physics. The authors note that careful assessment of the long-term results of radiotherapy is showing its limitations Some cutaneous diseases of chronic inflammatory type should only be treated by radiation if other methods fail; even then, treatment will be successful only in a proportion of cases. The trend in treatment is towards lower dosage. Where suberythema doses used to be prescribed it is now usual to specify 75r or even less. The chapter on tinea capitis has been improved by the inclusion of a number of diagrams illustrating the Kienböck-Adamson technique for depilating the whole scalp, and some good new photographs have been added.

THE LANCET

LONDON: SATURDAY, SEPTEMBER 6, 1947

Brain and Mind

This year there have been three publications of importance to those interested in the perennial problem of the relationship of the brain and the mind. Prof. E D. ADRIAN *has delivered the Hughlings* Jackson lecture[1] and the Waynflete lectures[2]: and, to coincide with the 17th International Congress of Physiology, the Physiological Society has republished Sir CHARLES SHERRINGTON's classical work *The Integrative Action of the Nervous System*, with a new foreword by the author.

The Waynflete lectures on the physical background of perception give an up-to-date account of the physiological processes underlying the conduction of sensory nerve-impulses from sense-organs to cerebral cortex and their reception there, as these functions have been illuminated by modern methods of recording minute changes of electrical potential. All nerve-impulses in sensory nerves are found to be of a fairly simple kind, and there is no substantial difference between those excited by touch, for example, and those concerned with hearing and vision. "The mental result must differ because a different part of the brain receives the message and not because the message has a *different form." The function of the* cerebral cortex seems to be to recognise patterns, both temporal and spatial, presented to the various senses. "We can recognise a tune," ADRIAN says, "whether its pitch is high or low, and we can recognise a triangle or a letter whatever its size and whatever the position of the image on the retina. Now this must mean that there is no need for particular sensory endings or particular pathways to the cortex to be excited; for the recognition of the pattern all that seems to matter is that the excited regions should have certain general relations to one another." The power to recognise such relations, which correspond in consciousness to quite abstract ideas, is not a prerogative of the human mind: a rat can be trained to recognise and respond to triangularity. "The rat seems able to differentiate the figure, so that the three angles are the only feature of it that matters and the absolute size and the position in the retina do not." This seems to imply that all the physiological disturbances excited in the cerebral cortex by triangles, whatever their size and position, possess something in common which is somehow selected for attention and reaction. At present it is difficult to conceive of the nature of a neural process which underlies the recognition of relationships abstracted from the things that are related and independently of any stable position of the excited neurones in the cerebral cortex.

It is equally difficult to imagine the neural basis of memory. LASHLEY's experiments with rats, quoted by ADRIAN, have made this seem more mysterious than ever. "Lashley has investigated the learning and retention of various habits in the rat and finds that, as far as simple associations are concerned, at least half the cerebral cortex can be destroyed without effect, and that half may be in any part of the cortex . . . we are forced to conclude that no one part is essential. And yet some part is essential, for the rat cannot solve anything if the whole cortex is destroyed." The solution, as LASHLEY has suggested, might be that the memory traces are everywhere, the whole cortex being a series of resonating mechanisms. ADRIAN, as a physiologist, is reluctant to accept the alternative—"that memories are not stored anywhere"—but this hypothesis may need to be considered seriously. When we look for the site of storage of "memory traces" we are making the assumption that these are states of neurones and therefore to be found somewhere in the brain They might, however, be psychical, and therefore not in the brain at all. Many years ago BERGSON in *Matter and Memory* put forward the view that the function of the cerebral cortex is to evoke and direct towards reality a memory "absolutely independent of matter"

It is not only on the afferent side that the nervous system is concerned with patterns: these appear in motor activity also. Thus, ADRIAN notes, "we may learn a skilled movement by employing certain muscles and therefore certain groups of nerve-cells in the motor area of the brain, but when we have learnt it we can carry out the movement with an entirely different set of muscles and nerve-cells—we can write our name with a pencil held between the toes when we have learnt to do it with the fingers." These motor patterns assume a purposive character. If the frontal area is stimulated electrically the nervous system behaves as though its object were to turn the gaze to the opposite side, for "if the head is free the eyes remain central in their orbits and the head turns. If the head is fixed the eyes turn instead."[1]

Thus we are introduced to a nervous system which is much more plastic than used to be supposed. It is capable of representing sensory patterns and putting into action motor patterns which are largely independent of particular groups of neurones, and indeed "it is possible," ADRIAN says, "that besides these relatively insulated, well-organised pathways, the more diffuse connections of the higher levels may depend to some extent on the electrical fields which are generated by active areas."

But to return to the psyche—surely that pale ghost was laid once and for all by the 19th-century materialists! How many psychiatrists, even, would claim more for it than that it is a convenient term to describe those neural functions that give rise to consciousness? Nevertheless the bland dismissal of mind as a mere epiphenomenon of neural function was made at a time when almost nothing was known of the finer details of the activity of the nervous system. How significant it is, therefore, that the pioneer of such knowledge should now regard the psyche as necessary on scientific grounds for a complete explanation of experience. "Integration," writes SHERRINGTON, in his new foreword,[3] "has been traced at work in two great, and in some respects counterpart, systems of the organism. The physicochemical (or for short physical) produced a unified machine from what without it would be merely a collocation of

St. Mary's Hospital

VACCINES

For Respiratory Affections

ANTI-CATARRH VACCINE

The ideal time for commencing prophylaxis against the common "cold" is during September. Three graduated doses, or six if preferred, with an interval of from 7 to 10 days between each, are recommended. The vaccine especially designed for the purpose is "Anti-Catarrh Vaccine," containing *M. Catarrhalis*, with *Pneumococcus, B. Pneumoniæ, B. Septus, B. Influenzæ*, and *Streptococcus.*

Supplied in sets of 3 or 6 graduated doses, and in ampoules of 1 c.c.; also in bottles of 10 c.c. and 25 c.c.

INFLUENZA VIRUS VACCINE

A purified and concentrated vaccine for protection against both types A and B influenza virus. It is recommended that a first dose of 1 c.c. be administered in September, or early in October, followed by the same dose after two or three months. To afford protection against the secondary as well as against the primary infection, Influenza Virus Vaccine may be combined with Anti-Influenza Vaccine (mixed).

Supplied in 1 c.c. ampoules

These Vaccines are prepared in the Wright-Fleming Institute of Microbiology (late Inoculation Dept.), St. Mary's Hospital, London, W.2. Further particulars on request.

Sole Agents:

PARKE, DAVIS & CO., 50 BEAK STREET, LONDON, W.1

Laboratories: Hounslow, Middlesex *Inc. U.S.A., Liability Ltd.*

has been named chronic hypoplastic anæmia by CKFAN and DIAMOND.[11] True aplastic anæmia olving all the elements of the bone-marrow is more mon in older children. Leukæmias in childhood usually acute, and since they are often aleukæmic, y will be missed if bone-marrow biopsy is not done. y gives a confident list, but anyone with practical erience will admit that there are still many children h apparently primary anæmias that do not fit into known scheme, and much more work with ern techniques needs to be done before these malous cases can be adequately classified and ted. A good idea of the size of the anæmia problem iven by the fact that BATY's cases made up 34% ll admissions. In the U.S A. infection is thought e the main cause ; in present-day Britain, on the er hand, opinion might well favour malnutri- n since the child's rations are sometimes only just quate and many mothers are anæmic

n discussing diagnosis, SMITH [6] describes techniques estimating red-cell volume and erythrocyte ility by using finger blood ; he gives useful tables normal ranges including one for sternal bone- rrow, but here he does not make clear the important phocytosis that occurs between one and three rs of age. SMITH would like to see more use made radiography of the bones with observation of the nges in the marrow spaces, and he emphasises the ue of watching the response to a properly planned rse of treatment with iron and then liver or folic d—in that order, never *together*. PONCHER [6] cribes the treatment in detail, stressing the impor- ce of preliminary diagnosis. He reviews the dence for the addition of copper to iron in the atment of iron-deficiency, and he concludes that a r patients who do not respond to iron alone will efit from the addition of 1 ml. of 0·5% copper phate solution per kg. body-weight daily. The stion of accessory metals in iron treatment has ently been revived by WINTROBE and co-workers,[12] o report that the addition of cobalt assisted the lisation of iron in artificial infections PONCHER ees with ZUELZER that it is useless to expect a ponse to iron in the presence of infection. He nks that ferrous sulphate is the best compound give in iron-deficiency, the dosage being gr. 4–6 26–0 39 g) daily during the first two years of life, 6–8 (0·39–0·52 g.) daily from two to six years, and on. Iron given to children produces a reticulocyte sponse on the 7th to 10th day, and by this and rise in hæmoglobin the efficacy of the iron prepara- on can be checked ; the case should be reviewed there is no proper response. The rare patient with rnicious-type anæmia responds to parenteral liver to folic acid (5–20 mg. daily) Ascorbic-acid ficiency is known to depress erythropoiesis.[13] æmia due to this cause has its greatest incidence the first two years of life and should be watched ; it will not respond to iron or liver but requires corbic acid in adequate doses of 100 mg. or so daily. or other anæmias treatment follows the usual lines. ONCHER advises splenectomy for congenital hæmo- tic icterus even in early childhood, and CONRAD and SCHMIDT [14] have reported a successful splenectomy in a child aged ten weeks, the diagnosis having been made at the age of seventeen days.

All the speakers in this symposium join in execrating the "blunderbuss" remedy for anæmia—the "compound" pill, elixir, or capsule containing iron, liver, vitamins, folic acid nowadays, and much else besides, usually in ineffective doses. As PONCHER puts it: "preparations of this type increase the cost of medical care and minimise the careful evaluation of the cause of the anæmia which is so important to well-conceived and intelligent treatment." But if doctors did not use these proprietary blunderbusses, pharmaceutical firms would cease to make them. In their management of anæmic patients doctors are too readily influenced by advertising literature and uncontrolled "favourable clinical reports"; it should be borne in mind that liver or folic acid is rarely needed in the treatment of anæmia in childhood, and that, though iron and ascorbic acid are a valuable combination, other mixtures should be used only when there are specific indications.

Annotations

CONVALESCENT HOMES

THE Institute of Almoners have done a useful piece of work in surveying and reporting on convalescent homes in England and Wales.[15] Our convalescent accommodation has long been an unknown quantity, and though the almoners do not provide the detailed list of homes which would be welcome they give tables of the numbers of homes to be found in various areas of the country and show the general distribution on a map. In all, there are some 318 homes, with 14,190 beds.

A convalescent home is defined as one which admits patients who have passed the acute stage of their illness but still require some medical and nursing supervision during the later stages of their recovery. Nowadays there are good grounds for regarding convalescence as a period of active reablement, but few of the existing homes are equipped or staffed for this purpose. Only 5 of the homes visited had the services of an occupational therapist, and though education was usually provided in the long-stay homes for children, it was not universal. Only 52% of the homes had libraries, and the quality of the books was not always good. Breakfast in bed was the rule in only 6 homes, though the staff of almost half of those visited were willing to give breakfast in bed when required. The time of rising was usually between 7.30 and 8 A.M., but in one Roman Catholic home the children rose at 6.30 A.M., and in another children's home in the Midlands at 6 A.M. Less than half the homes had a compulsory-rest rule in the afternoons, though the rule was observed in most of those for children. In 10 homes patients were not allowed to rest on their beds or go to their rooms during the day. Diet was often a cause of complaint; in several homes the last meal of the day was early, and not followed by a hot drink at bed-time. Most homes admit patients for a fortnight, but will extend the period if necessary; in 20 the period was firmly limited to two weeks.

The shortage of homes is such that waiting-lists are very long, and patients wait for places for periods varying from three weeks to over three months in summer; in winter or bad weather the delay is less. Homes for mothers with babies and for adolescent boys are particularly scarce, and so are homes taking more serious

commensal organs. The psychical creates from psychical data a percipient, thinking and endeavouring mental individual . . . not that the physical is ever anything but physical, or the psychical anything but psychical. . . . In the sequence of events (in the nervous system) a step is reached where a physical situation in the brain leads to a psychical, which however contains no hint of the brain or any other bodily part." Brain and mind are integrated together—"the last and final integration." As SHERRINGTON points out, "the discussion of this liaison between two incommensurable factors" can be avoided either by an idealism that makes everything psychical or by a materialistic monism that reduces body and mind alike to energy. He, however, remains a dualist, and concludes: "That our being should consist of two fundamental elements offers I suppose no greater inherent improbability than that it should rest on one only."

Thus neurophysiology, pressed far enough, ends in a philosophy not unlike that to which modern physics seems to be tending As MARTIN JOHNSON shows in a recent book,[4] the old matter of the materialist philosophers disappeared long ago. It has been replaced by "structures" represented by equations. It may be possible and indeed necessary to study a physical structure without any knowledge of what composes it Two mutually incompatible structures—a wave and a particle—may characterise the same "thing" because there exists no "thing" beyond the structures. Causation in its old familiar sense seems also to be disappearing, and JOHNSON at least makes no claim that the conceptions of physics are applicable to the phenomena peculiar to life and mind. Biology and psychology will need their own concepts and are free to make them. We have crossed an ocean and see before us the dim coasts of a new world of thought.

Anæmia in Childhood

THE advances in technique and classification that have clarified our ideas on the causes and treatment of anæmia in adult life have only slowly been applied to anæmia in childhood. The sections on anæmia in pædiatric textbooks are often patchy, and mixed syndromes, like Von Jaksch's anæmia, are still described. The lability of the blood-picture in young children, the wide range of variation, and the paucity of information about normal ranges have all played their part in this delay; bone-marrow puncture—a keystone of modern hæmatological diagnosis—has only recently been applied in children's diseases, and here again much has yet to be learnt about normal variation [5] There are, however, signs that the anæmias of childhood are at last being more rationally classified.

The progress made is well summarised in a symposium held at San Francisco last year and lately published.[6] ZUELZER, dealing with pathogenesis, points out that the features of childhood anæmias are conditioned by the peculiarities of rapid growth, lack of nutritional reserves, and susceptibility to infection that characterises this period of life, and that there are no special anæmia-producing mechanisms. Thus an iron-deficiency anæmia is common in children because hæmoglobin must be found not only to replace physiological losses but also to keep up the level in a rapidly expanding blood-volume, whereas in the adult production balances destruction and the blood-volume is practically stationary. The physiological anæmia of infancy has two causal factors. First, erythropoiesis is stimulated by anoxæmia, so, when the change takes place from placental to pulmonary oxygenation of the blood and the oxygen tension in the tissues increases, erythropoiesis is reduced; secondly, the blood-volume at the same time begins to expand rapidly and more red cells than ever are needed. It is in the latent period, while erythropoiesis is readjusting itself, that the anæmia occurs, and it is naturally more severe in the premature infant. Such an anæmia will not respond to iron since it is the number, rather than the hæmoglobin content, of the erythroblasts that is inadequate Adjustment is effected by the anæmia itself lowering the oxygenation of the marrow and so stimulating erythropoiesis.

The child, like the adult, needs iron and the liver factor (erythrocyte-maturing factor) for proper erythropoiesis. The full-term child has acquired from its mother a store of iron sufficient to last until it can obtain iron from the diet, and this store is particularly important since milk is poor in iron. The premature infant soon exhausts its store and becomes anæmic; the same thing happens—as MACKAY [7] pointed out—in the full-term child of a woman who has had iron-deficiency anæmia during pregnancy. Infection, however, is the major cause of such anæmia. Infection interferes with the absorption of iron by causing anorexia, vomiting, and diarrhœa; recent work with radio-iron shows that infection also causes ingested iron, including iron given therapeutically, to be held in the liver and elsewhere and only partially released for utilisation in the marrow,[8] and this latter is probably the more important effect Insufficiency of the liver factor is much less common, true pernicious anæmia does not occur in infancy,[9] but temporary deficiencies leading to a megaloblastic marrow occur in some patients with cœliac disease and in a syndrome recently described by ZUELZER and OGDEN.[10] Infection, deficient diet, prematurity, and combinations of these were held responsible for 90% of 514 cases of anæmia in children—i e., with less than 4,000,000 red cells per c mm. and 70% (10 g. per 100 ml.) hæmoglobin—seen by BATY[6] at the Boston Floating Hospital. The causes of the remaining 10% are those familiar in adult anæmia—hæmolysis, hæmorrhage, primary and secondary hypoplasia of the marrow, leukæmias, congenital abnormalities like hæmolytic icterus, sickle-cell anæmia, and Mediterranean anæmia There are some diseases peculiar to this age-group; such are the anæmia of erythroblastic disease due to Rh incompatibility, and a curious hypoplasia of the erythroblastic marrow without involvement of leucocytes or platelets which seems to be congenital, affects infants, ponsibility of the Hospitals Authority, while the berculosis service remains "to be administered parately but in coördination with the general services" the Northern Ireland Tuberculosis Authority ablished last year. This leaves less to be done by local health authorities, and in practice their scope ms to be limited to providing maternity, child-welfare, d home-help services, and to the local administration sanitary inspection and epidemiological control. e official explanation of the Bill states the conditions the use of private rooms in hospitals more clearly n these have yet been defined in England. It says cifically:

> 'Hospital schemes may provide that apart from his dical condition any patient in hospital may, by making pecial payment, be accommodated in a single ward or other all room, and that by making a payment calculated to er the whole cost of his maintenance and treatment and agreeing to pay the fees of his doctor, a person may be mitted to a private ward as a private patient of the doctor cerned."

On the whole the Bill as presented appears to offer a cticable adaptation of the earlier schemes to Northern land's needs, and seems also to have made most of the cessions asked by the doctors here—with the single portant exception that it retains the prohibition of e of practice goodwill.

THORACO ABDOMINAL APPROACH FOR GASTRECTOMY

THE limitations of the abdominal approach to tumours the cardiac end of the stomach, particularly those ich have involved the lower œsophagus, have long en evident. Many early tumours have been left resected because of the difficulties of operating by is route, and many patients in whom tumours of this ion have been resected have died because of the ficulties of making a good œsophageal anastomosis m the abdomen. Posterolateral thoracotomy with nsphrenic exposure of the upper part of the stomach s overcome the difficulties of œsophageal exposure and astomosis, but this route has two defects—the difficulty adequate dissection near the pylorus and closure of the odenum in cases requiring total gastrectomy; and the convenient angle at which the stomach is encountered hen working from above downwards.

The thoraco-abdominal approach reduces these difficulties to some extent. In this modification the incision rough the bed of the eighth or ninth rib, or through intercostal space, is continued across the costal argin into the abdominal wall for a varying distance. his procedure is made somewhat awkward by the stomary position of the patient during a postero-teral approach—that is, lying on the side with a rward or ventral tilt. The abdominothoracic approach as first successfully used for total gastrectomy and for cision of the cardiac end of the stomach by Ohsawa[1] ho recorded his cases in 1933. He made a formal pper paramedian incision, and from near its upper d extended the incision into the seventh intercostal ace. Subsequent workers who tried this incision with e patient supine found that the œsophagus was still t great depth and its adequate visualisation was somehat hampered by the interposition of heart and perirdium. Garlock[2] urges that if one is to obtain the aximum help from the abdominothoracic approach he patient must be made to lie on the right side with a ackward or dorsal tilt of 15°, and be fixed in this osition by a strap round the hips. He recommends short left lateral rectus incision, just large enough to dmit a hand for preliminary exploration of the abdomen, nd, if no contra-indication is found, the upper limit of he incision is continued into the eighth intercostal space as far back as the posterior axillary line. The wound is widely spread open and the diaphragm divided down to the œsophageal hiatus.

At the Oxford meeting of the Association of Surgeons early in July, the treatment of carcinoma of the lower œsophagus and cardiac end of the stomach was discussed, and P. R. Allison favoured the thoraco-abdominal approach while N. C. Tanner preferred the abdomino-thoracic route. Tanner advised a preliminary transverse epigastric incision from mid-line to the tip of the ninth costal cartilage rather than the lateral rectus incision recommended by Garlock; he had found that the exposure was sufficient to dissect the subpyloric glands and close the duodenum with ease. This approach gives an excellent "en face" view of the stomach and allows the surgeon to get near enough to the œsophagus to make œsophageal suturing comfortable and safe. Tanner thought it the best of all approaches to the spleen, pancreatic body and tail, and left gastric pedicle. and he said it gives excellent access for the jejunal mobilisation required in the construction of a Roux loop. Since the abdominothoracic route does not bring the operator quite so close to the œsophagus as the posterolateral thoracotomy, the latter incision is still to be preferred for the extirpation of primary carcinomata of the lower œsophagus which are above the level of the cardia. In such resections the final anatomosis can rarely be much below the level of the aortic arch, and furthermore dissection of the pyloric end of the stomach is unnecessary because only minor gastric resections are usually required. For the far more numerous cases of primary gastric carcinoma which are less than 4 cm. from the cardia, or which invade the œsophagus, the abdominothoracic approach is the best.

THE ADMINISTRATIVE INTERNSHIP IN THE HOSPITAL

A "manual and guide" on this subject has been issued by the Joint Commission on Education, Chicago. It represents an attempt to survey the present position of training in hospital administration in the United States. For the English reader too much is taken for granted, and the text is difficult to elucidate. For example, it is stated in the introduction that "the educational programmes that have been established are not identical in character, yet they have many common characteristics. Each requires a year of residence study followed by a year of supervised internship in a hospital. All but one require graduate standing for entrance." It is no doubt clear to American readers what is meant by residence study, for the manual deals exhaustively with training during the year of internship, but gives no indication of the curriculum during the previous year, or even of the place of residence. From comments on p. 2 it might be deduced that the preliminary year was spent in hospital, but the phrase "not infrequently he has been enrolled with advanced students of business methods" makes this deduction suspect.

When he arrives at the hospital for his intern year the student is expected to participate in the work of all departments. However, as regards the obstetrical department and the work of the visiting and resident staff, "only observational assignments are recommended."

At the end of his intern year the student is not required to pass any examination, and presumably he has already received his diploma or other qualification. His worth is assessed by the chief executive of the hospital on the basis of the progress he has made during the year, and if this is satisfactory he is no doubt qualified and independent. It is interesting to note the present trend of thought in the United States on training in hospital administration. A similar development is likely in this country, and it is important that we should know where we are going.

[1] Ohsawa, T. Arch. jap. Chir. 1933, 10, 605.
[2] Garlock, J. H. Surg. Gynec. Obstet. 1946, 85, 737.

cases such as cardiac and gastric conditions and patients with tuberculosis. Most homes refuse cases needing bed-treatment or nursing attention at night. The almoners note that this leads to wastage of nurses, for some homes with several nurses on the staff make this condition. Some homes have a bare institutional look; others provide long minatory lists of rules which take no account of the real welfare of the patient.

The almoners note that there is a need for more convalescent homes, particularly in north-east England. The classes most poorly catered for are mothers with babies, children, adolescent boys, patients with severe heart trouble, asthma, pulmonary tuberculosis and other chest complaints, fits, or skin diseases, and those needing more complicated treatment, dressings, or special diet. Holiday and rest-break homes are also needed. Many homes could be brought up to modern standards if altered and adapted, and furnished more cheerfully. A friendly reception, the almoners say, is highly important; and patients should be encouraged to breakfast and rest in bed, especially during the first week. Hours of rising should be later, and there should be plenty of resting-places, in and out of doors. The length of stay should be determined only by the patient's needs; expert advice should be sought on diet; and occupation and recreation, as well as other methods of reablement, should be extended. Finally they suggest that there should be a central advice service to coördinate the work of all convalescent homes, to set up standards, and to give information about organisation and staffing.

Since the moment is not too propitious for extending services, it might be useful to consider how our existing convalescent homes could be used to the best advantage; and since " convalescence " three months after the illness is rather unsatisfactory, it might be well to decide what types of patient should have first claim on available beds. Children who would otherwise return directly to slum areas should surely be among the first considered, and so should mothers of families who would otherwise go straight back to domestic chores. Young people in the growing years, old people living alone, and patients with pulmonary tuberculosis all seem to deserve some preference. If these needy cases were served first it is possible that they could also be served at once.

MINISTRY OF HEALTH STATEMENT ON STREPTOMYCIN

THE Ministry of Health announce that the preliminary results of the streptomycin trials organised by the Medical Research Council have proved sufficiently encouraging to justify the view that, as supplies of the drug permit, patients suffering from tuberculous meningitis or miliary tuberculosis should be given the opportunity of receiving treatment with the drug.

Streptomycin is the best drug at present available for the treatment of these conditions, but it prolongs life and relieves symptoms in only a proportion of cases, and it is too early to say whether it ever produces a permanent cure.

The production of streptomycin in this country is still very limited; but additional supplies obtained from the United States have made it possible to allocate some each month to certain medical schools for use in teaching or associated hospitals. Supplies are available at the moment in the United Kingdom for about 150 beds. The cost of the streptomycin is still very high, and for the time being the drug will be distributed by the Government to the medical schools free of charge.

In view of the limited experience of treatment with streptomycin in other conditions, the medical schools have been asked for the present to restrict treatment with the drug to cases of tuberculous meningitis and miliary tuberculosis. It is not recommended for chronic pulmonary tuberculosis.

Tuberculous meningitis and miliary tuberculosis be treated with streptomycin at the following hospitals:

ENGLAND

Liverpool.—Alder Hey Children's Hospital (6 children's beds) and Royal Southern Hospital, Fazakerley (3 adult beds).

Sheffield.—Children's Hospital, Western Bank, Sheffield, 10.

Newcastle.—Royal Victoria Infirmary.

Bristol.—Bristol General Hospital, Bristol, 1.

Manchester.—Royal Infirmary.

Birmingham.—Children's Hospital, Ladywood Road, Birmingham, 16.

Leeds.—General Infirmary and St. James's Hospital.

London.—The Middlesex Hospital, W.1, St. Bartholomew's Hospital, E.C.1, The London Hospital, E.1, St. Mary's Hospital, W.2, St. Thomas's Hospital, S.E.1, and Guy's Hospital, S.E.1.

WALES

Cardiff.—Isolation Hospital.

NORTHERN IRELAND

Belfast.—Whiteabbey Sanatorium, Whiteabbey, and Purdysburn Fever Hospital, Purdysburn.

Similar arrangements are being made in Scotland and details will be announced shortly.

Practitioners who have a case of suspected tuberculous meningitis or miliary tuberculosis should get in touch direct with the nearest convenient hospital on this list, or (in the case of hospitals in the London area) with the Emergency Bed Service (telephone Monarch 8515).

This scheme does not in any way affect the arrangements already made by the Medical Research Council for the treatment in certain hospitals of cases of meningitis due to *Hæmophilus influenzæ.*

NATIONAL HEALTH SERVICE FOR NORTHERN IRELAND

Northern Ireland, in its turn, is now to create a national health service, and the Bill has just been published. In the main, the provisions follow the pattern already familiar in the English and Scottish Acts. But the size and population of the six counties is no greater than that of some of the separate regions into which England has been divided for hospital planning and administration, and this has permitted simplification of the administrative structure. Thus instead of a number of regional hospital boards there will be a single Hospitals Authority, placed in charge of all existing hospitals, and entrusted with providing (by fresh building or by reorganisation) a full service. Much like the regional boards in England, this authority will be constituted by the minister after consultation with the university, the medical profession, the local authorities, and the hospitals both voluntary and rate-aided. Again, instead of separate local executive councils in most health-authority areas, Northern Ireland is to have a single General Health Services Board, *half professional* (medical, dental, and pharmaceutical) and half lay. As in England and Scotland, there will also be local medical, dental, and pharmaceutical committees in each health-authority area.

So far the scheme follows the earlier models closely. But the official document circulated in explanation of the Bill contains indications that some of the amendments vainly sought in London have been conceded in Belfast. For instance, there is no mention of a basic salary for the general practitioner; " every doctor will be paid according to the number of persons—men, women, and children—who have chosen him as their family doctor." Also in so far as inquiries are concerned into " allegations that any person providing professional services is inefficient or unsuitable "—a final appeal lies to the High Court. The General Health Services Board will be the employing authority for general practitioners and will also be responsible for planning and building health centres (a responsibility which in England is placed upon the local health authority). The pathological, bacteriological, and blood-transfusion services are made the

Reconstruction

TREATMENT IN PRIVATE WARDS
UNDER THE NATIONAL HEALTH SERVICE

FROM A CORRESPONDENT

The Minister of Health has not yet given any clear indication of his intentions about pay-beds. The Act empowers him:

(i) To reserve single rooms and small wards for patients who undertake to pay part of the cost—so long as he is satisfied that such rooms and wards are not for the time being needed on medical grounds by other patients

(ii) To set aside special accommodation for patients who undertake to pay the whole cost, including overheads. But nothing is to prevent accommodation thus set aside being used by any patient who urgently needs it on medical grounds, and whose need cannot be met otherwise.

In connexion with (ii) the Minister may allow any doctor on the hospital staff to arrange for the treatment of his private patients, and regulations may prescribe the maximum fees to be asked.

In the debates on the Bill Mr. Bevan justified these provisions on the ground that exclusion of paying patients from hospitals would encourage something of a black market outside the service. A patient should be free to seek professional advice from whom he will; and, since inpatient treatment will often be necessary, it should be made easy for doctors to bring their patients to the hospitals, and receive remuneration for their care.

So far so good. But here agreement ends, and one can discern widely different ideas as to terms and conditions. Many medical men are assuming that these will remain much the same as those prevailing in recent years. But in the committee debates on both the English and Scottish Bills a good many voices were raised in protest against a continuance of a system whereby those who can afford to do so are permitted to secure the special privileges of privacy and the advantages commonly associated with the private wards. Too often, it is urged, the poor person whose need of privacy is great is relegated to the ordinary wards while the private patient gets privileges to which he has no medical claim. A higher standard of catering, a higher ratio of nurses to patients even when the hospital is otherwise short of staff—can such discrimination have any place under a national service whose object it is to serve equally all in need, irrespective of means? In the debate on the Scottish Bill it was suggested that the charge for privacy should be minimal—a figure of 5*s*. or 10*s*. a week was mentioned—with the clear implication that all special privileges should be eliminated.

No doubt it would be difficult for the Minister to modify drastically the present system. But he will certainly be pressed to do so.

DEVELOPMENT OF PAY-BEDS

Much of the difficulty arises out of the circumstances attending the growth of the pay-bed system over the last fifty years.

The first paying patients' home was established by St. Thomas's Hospital as long ago as 1881. The intention was then to cater for people of small means who could not afford to go to a nursing home. As the years have passed this primary intention, while always prominent, has been modified by the need to offer the advantages of hospital to those with the higher ranges of income as well as to those whose income does not much exceed the limits set for the ordinary wards.

In the early 'twenties fears were expressed lest the rapid increase of pay-beds might conflict with the charitable basis of the voluntary hospitals, and a comprehensive inquiry was set on foot by the King's Fund. Reporting in 1928, its Pay Beds Committee approved of the provision of hospital facilities for the middle classes but emphasised two conditions—namely, that capital should be found without drawing on hospital funds, and that the paying patient should meet the full cost of maintenance, any surplus to be devoted to the needs of the hospital. (The latter recommendation was modified in regard to borderline patients, who might be allowed to pay less than the full cost, provided that the unit as a whole did so.)

In the circumstances of the time these were excellent recommendations, and pay-bed development in the voluntary hospitals has largely followed them. But twenty years have now passed since the report of the Pay Beds Committee, and three main tendencies have become noticeable. First, the wholly admirable anxiety to safeguard the charitable funds of the voluntary hospitals from abuse has had an unexpected result in that it has favoured collection of single-bed rooms into separate pay-blocks, thus making it unnecessarily hard to assign them according to medical need. Consequently pay-bed blocks today consist predominantly of single rooms, while the ordinary wards remain multiple units only slightly modified by the provision of a few single rooms. Clearly this tendency ought now to be reversed. Secondly, the voluntary hospitals continued to be hard pressed for funds, and in many cases began to look to their pay units for additional revenue. This helped to open the way to a third tendency—namely, competition with the more expensive nursing-homes in many details affecting the patient's comfort. Medical men have more and more desired to bring their better-class patients into the hospitals for the sake of facilities lacking in the nursing-homes; but this has had the indirect result of encouraging the hospitals to emulate the standards of the nursing-homes in many minor matters, and has accentuated the divorce between pay and ordinary wards. The combined effect of the second and third tendencies noted above has forced up the weekly charge for many pay-beds to a figure which means that the ordinary middle-class patient has become increasingly unable to meet the cost, and he is therefore thrown back upon the ordinary wards.

The rise in cost still continues, and the charges for pay-beds in the London teaching hospitals are reaching figures so high as to call in question the practicability of asking the full cost, or anything like it, under the National Health Service. The Minister may therefore be compelled to take power (by amending the Act) to charge part rather than the whole of the cost for private accommodation. To do so would be to abandon outright the conception which is now firmly rooted in the hospital world, and which has found its way into the Act, that the charge to the paying patient must cover the cost. But since this conception is based on the idea of safeguarding charitable funds, it no longer has force.

PROVIDENT SCHEMES

Some time ago efforts were made to find a means of enabling middle-class people to insure against hospital charges. The Hospital Saving Association had been founded in 1922 for the ordinary patients, and soon afterwards the British Provident Association was launched to cater for the middle classes. A similar scheme was established at Oxford. In the middle 'thirties further discussions in London led to the establishment by the King's Fund of the London Association for Hospital Services on similar if rather simpler lines. The membership of these schemes and of others in various parts of the provinces remains, however, relatively small, and is by no means to be compared with that of the contributory schemes. The explanation is of course that to be of value to the subscriber such a scheme must, unlike the contributory schemes, provide for a schedule of payments

SCIENCE AND THE CRISIS

FUNDAMENTAL research or operational research—on which should our emphasis now be laid? This was the big question that came out of the British Association's meeting just concluded at Dundee.

Sir Henry Dale, O.M., in his presidential address, began by speaking of the astonishing achievements of science under the stimuli of war—the rapid development of radiolocation, the headlong progress of aeronautics, the utilisation of penicillin, the discovery of 'Paludrine,' and the solution of problems arising from exposure of human beings to unnatural stress. These achievements came of intensive coöperative effort, and science must profit by its new experience of planning and organising to attain a particular objective. But there are other lessons of the war which Sir Henry thinks it at least equally important to discard: he sees a danger to science in a tendency to transfer, too easily and completely, to the activies of peace, the attitude to research and the traditions of its conduct that were acquired during those six years when most scientists in this country had to devote nearly the whole of their thoughts and efforts to practical problems presented to them for quick solution. "Does anyone doubt," he asked, "that to enable science now to render its best service to mankind, we need to take a long-range view and to give our first care to the extension of fundamental knowledge, unconstrained by aim at any practical objective?" Admittedly there are plenty of examples of practical research—conducted under conditions which left full freedom to follow side issues—opening the way to great fundamental advances. But to concentrate almost the whole of a rapidly growing scientific effort on practical applications and developments, as happened during the war, would correspond to reckless cropping of land without care to nourish the soil. He is not afraid that fundamental research will fail to win material support: "my fear is rather that we scientists ourselves may find it difficult to shake off quickly the spendthrift habit in research, the policy of trading for quick returns."

The other school of thought represented at Dundee argued that the need for operational research is today as great as in the war: it sees immediate mobilisation of scientific talent as the best—and probably the only—means of getting Britain out of her difficulties.

> "The present situation," said Prof. J. D. Bernal, F.R.S., "requires just that combined effort that was so effective in war. We can be certain that during the next few months and years we shall find ourselves confronted with a series of very uneven changes. We shall not follow the course of normal development. We must have a new technique, and operational research is just the instrument for the purpose. If we do not use it we shall not only cease to be an important Power—we shall starve."

In an interview with the *Manchester Guardian* (Sept. 1). Professor Bernal spoke of large numbers of scientists as at present largely idle or working at cross-purposes or against one another; he estimated that the key industries could get as many as 20,000 who are redundant or reduplicating each other's efforts, and another 20,000 who are at present superfluous, besides many from the military research departments. "We have the men and the technique. All we want is their use at all levels." The most hopeful line for quick results lies, he thinks, not so much in increasing production as in preventing waste: our whole system is shot through with unconscious waste. In a statement on Science and the Economic Crisis,[1] the Association of Scientific Workers, of which Professor Bernal is president, points out that if the average efficiency of the utilisation of coal were raised from 20% to 25% we should save the equivalent of 50 million tons annually. By far the best way to produce more food and goods from less imports is to introduce more economical methods of production. The war provided many examples of great difficulties overcome in weeks or months, which without science would have taken years. Today

> "short-period intensive research can make practical the use of substitute processes and materials to replace costly and scarce imports. A study of waste products in various industries, including waste heat, could lead to great economies in the use of materials. The development of systematic plans to attain a technical level in industry based on the best existing practice would bring quick and cumulative results. Scientific study of industrial organisation could improve efficiency output."

A scientific and technical effort on a scale many times that of the present is in the association's opinion by no means impracticable.

> "Without calling on the universities for more than advisory services and limited pieces of background research we have an immense fund of men and equipment in military research and in industry whose work, at least for the time being, could be turned over to immediate production problems. We are spending £60 million a year on war research, more than four times what is spent on Government civil research. Whether this assessment of priorities could be justified in any circumstances may be argued, but it is impossible to justify it when the safety of the country depends on the rehabilitation of our industrial economy."

After describing the organisation it thinks necessary to attain these ends, the Association of Scientific Workers pleads for early decisions and action. "The production of goods two or three years hence depends on research done this year."

POLIOMYELITIS STATISTICS

THE present outbreak of poliomyelitis has produced a total of 3127 cases in thirteen weeks, and, though the figures we quote on another page suggest that the corner has been turned, before it has spent itself the case-rate may well approach the 19 per 100,000 population recorded in the United States in 1946, when over 25,000 cases were notified.[1] However, there were times when notifications in New York reached 1000 per week; whereas in London the figure has only slightly passed the 100 mark. The fatality-rate here is not yet known, but in July it probably was of the order of 70 per 1000 notified cases. In the U.S.A. the fatality-rate fell steadily in the years 1943–46, all of which were years of relatively high prevalence, and it seems likely that much of the apparent rise in prevalence there resulted from more complete reporting and the inclusion of a greater proportion of non-paralytic cases. Certainly the focusing of attention on the disease has stimulated notification in this country, and analysis may show that there has been a steadily rising ratio of non-paralytic to paralytic cases among those notified. Differentiation between paralytic and non-paralytic cases would be possible if the notification form was made more explicit—a measure which may deserve consideration. In the few States of the U.S.A. which could supply this information, the percentage of non-paralytic cases notified in 1946 varied from 1·8 to 77; the highest percentages were reported in towns in epidemic areas, as would be expected, and it may well be that two-thirds or more of our present notified cases are non-paralytic.

THE INDEX and title-page to Vol. I, 1947, which was completed with THE LANCET of June 28, will be published with the issue of Sept. 20. A copy will be sent gratis to subscribers on receipt of a postcard addressed to the Manager of THE LANCET, 7, Adam Street, Adelphi, W.C.2. Subscribers who have not already indicated their desire to receive indexes regularly as published should do so now.

Alderman Miss A. Hudson (chairman); Drs. R. McG. Barron, J. Gordon-Wilson, E. W. Hall, B. S. Kent, R. C. Macqueen, L. H. Smith, L. A. H. Snowball.

East Ham
Mr. W. G. Davie (chairman); Drs. M. Barker, J. C. Bell, A. V. S. Davies, A. A. Fyffe, C. Rutter, J. S. Thomas, O. Thomas, H. G. Watters.

Essex
Mr. J. K. Wiseman (chairman); Drs. J. L. McK. Brown, C. Fox, J. A. Moody, H. N. Rose, K. V. Smith, J. D. Wells, R. A. Woodhouse.

Gateshead
Mr. C. Dixon (chairman); Drs. J. C. Arthur, A. MacArthur, May F. St. J. U. Millar, W. T. O'Brien, R. H. Smallwood, G. W. Spark, W. M. Wilson.

Great Yarmouth
Mr. H. S. Matthes (chairman); Mr. B. Adlington, F.R.C.S., Drs. A. S. K. Anderson, C. A. Dowding, E. A. Ellis, H. E. Filmer, I. W. Hockley, J. M. Smellie.

Hampshire
Alderman A. Lubbock (chairman); Drs. J. Clayre, D. G. Cooper, D. R. Gillies, G. H. Johnson, W. D. Keyworth, P. A. T. Lowden, J. T. Rowe.

Herefordshire
Mr. E. W. Maples (chairman); Drs. J. S. Cookson, C. J. C. Cotton, G. W. Dryland, F. S. Machin, F. O. T. Strange, R. G. F. Thompson, G. D. Tullis, C. W. Walker, H. Ward-Smith.

Hertfordshire
Mr. G. Rollo Walker (chairman); Drs. H. B. Dykes, R. Fisher, R. P. Gammie, J. S. Ross, C. M. Scott, N. G. Thomson, A. Wigfield.

Huddersfield
Mr. Lawrence Crowther (chairman); Drs. G. S. Broadbent, J. M. Gibson, J. W. Hirst, W. L. Ingham, L. B. Lucas, T. W. Smailes, W. E. Thompson, E. G. L. Walker.

Huntingdonshire
Mr. H. Street (chairman); Drs. D. R. Ashton, P. S. Connan, J. W. Ellis, J. R. Garrood, W. S. Grove, A. E. Staffurth, H. C. C. Veitch.

Ipswich
Mr. A. R. Saward (chairman); Drs. C. B. Bevis, R. O. Eades, M. W. Gonin, W. P. Grieve, R. S. Kay, R. D. McD. Morrison, R. J. Steeds.

Isle of Ely
Mr. W. Stewart Elgood (chairman); Drs. W. H. Carlisle, J. A. Hislop, G. H. Lucas, K. S. Maurice Smith, J. R. F. Popplewell, C. Thomas, W. M. Wilson.

Isle of Wight
Miss May O'Conor (chairman); Drs. L. H. Crosskey, P. A. K. Jones, F. R. B. H. Kennedy, J. J. O'Donoghue, L. F. E. Way, J. B. Williamson, H. S. H. Wood.

Kent and Canterbury
Alderman R. W. Rule (chairman); Drs. A. C. E. Breach, F. C. Cozens, D. A. Davies, Marjorie Day, E. C. Gross, A. Y. Milne, A. M. Pollock, A. T. Rogers.

Lancashire
Alderman Mrs. K. M. Fletcher (chairman); Drs. A. Campbell, J. J. Devlin, J. E. K. Keyms, A. Owen, J. P. Quinn, F. M. Rose, S. A. Winstanley.

Leeds
Alderman D. Beevers (chairman); Drs. J. Atkinson, I. G. Davies, F. F. Hellier, H. F. Hollis, J. Vaughan Jones, J. H. E. Moore, T. D. Pratt, J. E. Rusby.

Leicester
Mr. W. T. Tanser (chairman); Drs. J. A. Chapel, F. T. Doleman, E. W. Goodwin, W. E. Howell, B. C. Jennings, E. K. Macdonald, C. H. Parker, W. S. Russell, G. W. Taylor.

Leicestershire and Rutland
Lieut.-Colonel C. E. J. Freer (chairman); Drs. G. S. A. Bishop, G. L. Gately, A. Hamilton, T. M. Montford, C. O'Donovan, G. Purdy, L. Reuvid.

Lincolnshire (Holland)
Mr. H. H. Small (chairman): Drs. J. F. Cadas, R. E. Crockatt, J. E. Darlow, A. C. Dawes, N. V. M. Dodds, J. H. F. Pankhurst, A. S. Wilson.

London County
Mr. H. Lesser (chairman); Sir Allen Daley, Drs. P. Gray, J. Green, E. A. Gregg, C. G. Martin, J. F. Murphy, H. Robinson, M. Sorsby, H. H. D. Sutherland, R. S. Taylor.

Middlesex
Mr. Sidney H. Godfrey (chairman); Drs. R. W. Cockshut, D. F. Hutchinson, A. N. Mathias, C. D. Meadowcroft, R. L. Ridge, J. R. Richmond Ritchie, H. Vickers.

Norfolk
Mr. A. N. Wright (chairman); Drs. G. C. Gaynor, G. M. Goodwille, T. O. Hutton, H. Morrison, R. A. Norman, J. C. Pearce, E. I. Puddy.

Northampton
Mr. Malcolm Nash (chairman); Drs. J. G. L. Brown, L. D. B. Cogan, J. F. Kirwan, J. Orr, R. B. Roe, G. H. Thompson, A. Wilson.

Northamptonshire
Mr. B. L. Edwards (chairman); Drs. J. Arthur, W. F. Blackstock, W. King Churchouse, G. F. P. Gibbons, D. G. Greenfield, W. E. Lock, T. Murray Strang.

to doctors and surgeons. It cannot, therefore, adopt the simple pool principle of paying out whatever is paid in.

These schemes are, however, potentially very valuable, and it may be that if circumstances favour them, and if in particular they are able to offer a schedule of fees agreed with the profession under a "full cover" arrangement, they will grow rapidly as have similar schemes in America. Obviously their future is bound up with the terms and conditions upon which pay-beds are allotted in the new service. If, for example, the Minister abandons the principle of charging full cost for a pay-bed, and charges only the cost which is additional to that of ordinary ward treatment, the terms offered by the provident schemes will at once become much more attractive to prospective subscribers.

THE DILEMMA

No-one will envy the Minister and his advisers the task of laying down the lines for the future. He has to reconcile two conflicting groups of considerations. On the one hand, as he emphasised in defending the sections in the Act, he has to retain enough of the present structure to ensure that he does not drive out of the service—into revivified nursing-homes run for profit—much of the upper-class clientele in need of inpatient care. On the other hand, he has to guard against the division of the main hospital service into two grades, the one good, the other less good; and to eliminate as far as possible the tie-up between privacy and the means to pay for it. These things are much easier said than done, and the Minister's decisions may in the long run determine the whole quality of the ordinary hospital service.

In America it is generally believed that the path to progress is by the creation of grades, and that a constantly rising standard of humanity is best achieved by a filtering-down process: what is provided today for the well-to-do will be provided tomorrow for the rank and file. But in this country such an idea will find little support. It has been the pride of our greater hospitals that the treatment provided for the sick poor in the ordinary wards was second to none, and no effort has been spared to make it so. This single standard has been to some extent undermined by a desire to establish distinctions, and offer in the contributory and pay-wards privileges not to be had in the ordinary wards. But the Minister now has a chance to get rid of the monetary factors which have operated in this direction.

In balancing the two sets of considerations he may well be guided first and foremost by the latter group. He may decide, for instance, that single rooms shall in future be provided only in physical proximity to the ordinary wards, and that the whole set-up of the existing pay-blocks must wherever practicable be modified to bring them into line with this conception. This principle, as it became operative, would largely control the present tendency to favour the paying patient in the matter of nursing staff and quality of catering. When it comes to finance, he may decide that the hospital shall as such cease to have any financial interest in the scale of charges to the paying patient, and that the whole of any charges shall be forfeited to the Exchequer. Once the idea of meeting the full cost has gone, the Minister will have a free hand to determine the charge for privacy in the light of the need to bring the option within the range of all—for it cannot be denied that charges on anything like the present scales are prohibitive to many people whom privacy would benefit.

If he follows the line of thought suggested above, the Minister will no doubt feel that he must prescribe schedules of fees payable to doctors. For this there are precedents in the scales adopted by some of the hospitals, and there are the schedules of fees for patients of a modest income range agreed between the provident schemes and the British Medical Association. If the Minister were to take these latter schedules as a basis, and allow the profession a little latitude in respect of patients with incomes higher than those for which the schedules are designed, he would probably come fairly near to effecting the compromise to which he stands committed by the Act.

Special Articles

LOCAL EXECUTIVE COUNCILS

THE MEDICAL MEMBERS

WE publish this week a first list of the chairmen and medical members of the executive councils now being established under the National Health Service Act. Broadly speaking, there is to be an executive council for each area covered by a local health authority (a county or county borough), and its function is to provide the general-practitioner service and the dental, supplementary ophthalmic, and pharmaceutical services to which every citizen will be entitled under the Act. The chairman is appointed by the Minister of Health, and of the 24 members half are professional, 7 being appointed by the local medical committee, 3 by the local dental committee, 2 by the local pharmaceutical committee, 8 by the local health authority, and 4 by the Minister. The committees, which are the successors, in modified form, of the present insurance committees, will enter into contract with those general practitioners who are prepared to take part in the new service.

Barrow in Furness
Mr. F. W. Fryer (chairman); Drs. F. P. Healy, W. J. Liddle, G. H. Moore, R. W. Morrison, J. G. Seddon, J. Taylor, J. R. Turner.

Bath
Mr. P. W. Hopkins (chairman); Drs. J. Bennett, R. Craig, W. B. S. Crawford, B. Cuppage, C. Gibson, J. McQuistan, E. Scott White.

Bedfordshire
Mr. H. J. Weller (chairman); Drs. W. A. Barnes, J. C. Boyde, H. D. Clark, W. F. Eberlie, E. N. Graham, T. E. S. Lloyd, N. M. Munro, T. T. Rankin.

Berkshire
Sir Alexander Gray (chairman); Drs. J. A. Hill, L. Leslie, E. R. D. Maconochie, J. McCrea, G. F. O'Connor, J. A. Vernon, G. Wynne Thomas.

Birkenhead
Alderman C. McVey (chairman); Drs. H. C. W. Baker, R. W. Cowie, R. R. Knowles, W. Laing, E. L. Murphy, R. W. L. Pearson, A. V. J. Russell.

Blackburn
Mr. G. Hindle (chairman); Drs. C. M. Geddie, J. J. Jennings, J. Kyle, J. S. Malseed, D. O'Driscoll, C. M. Pearce, H. Southworth.

Blackpool
Mr. C. H. MacKeith (chairman); Drs. J. W. Aird, T. S. Blacklidge, C. R. Hardman, H. E. Martin, G. W. Murray, C. S. Philip, J. Stewart.

Bolton
Mr. G. C. Sumner (chairman); Drs. R. Beesley, H. W. Bowyer, R. A. Cranna, L. F. Evans, H. N. Savage, B. Thornley, A. L. Tinto.

Bootle
Major James Burnie (chairman); Drs. W. W. Boland, D. Brown, W. W. Emerson, I. Harris, T. M. Jones, C. J. C. Macquane, P. L. Regan.

Bournemouth
Alderman H. C. Brown (chairman); Drs. W. Asten, F. S. Coleman, C. E. Gautier-Smith, A. W. Hall, G. W. Hall-Smith, H. V. Mitchell, W. R. Pratt, Gordon Scott.

Brighton
Mr. A. E. Orbell (chairman); Drs. D. Archdale-Smith, C. Barrington-Prowse, J. Benyon, F. Eyton-Jones, T. A. Morrison, J. G. Thwaites, W. G. Thwaites.

In England Now

A Running Commentary by Peripatetic Correspondents

IF miners hew coal with a zeal half as fiery as that hown by farmhands getting in the harvest we ought to vercome our present economic difficulties with ease. he fierce energy of the West-country farm labourer aving corn has to be seen to be believed. He simply ill not stop till the job is done. It is not a question of vertime or to whom the crop belongs or whether the oss is watching; it is just primitive man wresting the means of subsistence out of a not too friendly planet. Heavily clad—usually in a thick vest and shirt, waistoat, long pants, and trousers to absorb sweat (notoriously a dangerous fluid, the cause of colds and rheumatism)—the team works stolidly but cheerfully on hour fter hour in the hot sunshine almost without a word unless it be one of polite encouragement to the clumsy mateur trying to help but mostly getting in the way.

Perhaps one day this will cease to be an industrialised ountry; the large towns dwindle and die. In the end we may revert almost exclusively to agriculture with a ane and healthy population of, say, 15 million self-upporting countrymen and a properly balanced economy. There are worse fates.

* * *

A holiday in Switzerland is a revealing experience. It shows not only difference between countries devastated by two wars and those enjoying peaceful development, but also some other factors contributing to the creation of this haven in Europe. Two examples may suffice.

We were invited to dinner at the house of a well-to-do colleague. After dinner the six children of my host, ranging from 4 to 11 years, looking well fed and displaying a hearty appetite, filed out of the room quietly. We found them a little later in the kitchen, all wearing clean household aprons and helping their mother wash up and put away plates, glass, and crockery. The youngest, a sweet little boy of four, normally full of affection and mischief, handled a very large plate, almost as big as himself, with surprising skill. All children understood German and French. They were full of beans yet very well behaved and obeying easily the quiet but firm lead of their parents.

A few days later I wanted a shirt laundered. I went to a laundry, which looked and smelled beautifully clean. The proprietress asked me "Is it urgent?" I said "Not really," and she replied "All right, it will be ready tomorrow morning about 9 o'clock." (It was between 9 and 10 A.M. when she said this.) I was so startled that I simply had to ask when it would be ready in case of urgency. The answer was "Between 8 and 10 o'clock tonight."—I forgot to mention that they opened at 8 A.M., had lunch-time from 12 NOON until 2 P.M., were open again until 6.30 P.M., another meal-time until 8 P.M., and—at least in the summer—reopened between 8 and 10 P.M. for the urgent orders. I had several lots washed there, all hand-laundered and beautifully done, with the greatest care. The price for a shirt thus treated was between Sw. fr. 1.00–1.20, but I believe regular customers paid less.

You are frowning, dear Editor? You are right, and I apologise. I am in the wrong column. This really could not happen in England now. . . .

* * *

Many of the younger men these days are much exercised over the apparently increased difficulty of winning the diploma of M.R.C.P. by examination. Actually the stenosis of the gateway is relative rather than absolute, for more people are getting through than ever before; it is only the crowd outside which has increased beyond all measure. In the stringency of war many people found themselves unable to do academic work, and they are now sitting for an examination which in the normal way they would have passed five years ago; another post-war phenomenon is of course that some of those who came to look on themselves as specialists are now trying in vain to convert the censors to the same happy view. Also, economic conditions which prevented all but the more determined from considering repeated trials for the M.R.C.P. in the pre-war years have now been palliated by the adequate Government grants for medical posts of registrar status.

If the number of applicants has increased in these ways, so too has the number of advertised appointments which require the diploma "or its equivalent." Membership has always been the recognised necessary first step in the specialised practice of clinical medicine; but it is now being looked on as an asset in such varied careers as pathology, psychiatry, and clinical or even laboratory research. For men engaged in academic or laboratory rather than clinical medicine it is difficult to see why the M.D., awarded by thesis, should not be considered an equivalent higher qualification. If this were generally agreed the strain on the M.R.C.P. examination might be partly relieved. It is obvious, too, that a proportion of the present clientele are unlikely ever to make satisfactory physicians, and in everybody's interest they should be told so.

Part of the present rush is certainly due to a wish to possess the golden letters before the new service comes in. Some candidates may share my nightmare of entering the regional office and seeing there one's old A.D.M.S., resplendent in a black coat and striped trousers. If he be of the younger set of "experienced military administrators" he will know that M.R.C.P. has four letters and L.M.S.S.A. five; but if he is someone of real seniority these finer points will be lost on him and the good jobs will go to the man with a straight tie and a stiff upper lip. So perhaps, rather than the toil of membership, it were better to sport with *Amaryllis*—she would at least see that a fellow was properly dressed.

* * *

Your recent article on the collection and disposal of London refuse leads me to think that a note on our local methods near Geneva might be helpful.

No fewer than three Authorities are concerned: my wife, responsible for combustible waste; myself, for non-combustibles; and a shadowy Commune of V— which is said to collect all refuse from the end of our lane on an unspecified day once a fortnight. (There is no evidence that this occurs, and the dumps of the optimistic at the end of the lane have attracted much unfavourable comment.) The following figures show the extent to which the various methods of disposal have varied during our tenancy:

Period	*Hopeful dumping in lane*	*Incineration*	*Lake tipping by "outboard" system*
May, 1947	25 %	75 %	Nil
June, 1947	Nil	80 %	20 %

The increase in the proportion incinerated was due to better knowledge of local markets and less eating out of tins.

Incineration is easy, requiring only a box of matches and no thunderstorms. Lake tipping is more complicated, the requisites being a boat, outboard motor, oars, colour chart, large-scale map, cold chisel, boat-hook, and fishing-rod. When a sackful of non-combustible refuse has accumulated, it is placed in the boat and rowed out to where the depth changes suddenly from about 10 feet to 300 feet, the old bed of the Rhone. The contour line on the map is indicated in the lake by a change from bluish-green to greenish-blue—hence the colour chart. (The outboard motor of course seldom or never starts and is there for historical reasons only, possibly connected with the prehistoric lake villages.) The rod and line are then brought into play to deceive the Gardiens du Port, since all dumping in the lake is illegal. (N.B.—It is important to use a rod and line, since fishing with a rodless line requires a licence and would attract rather than dispel any roving G.'s du P.) The tins are then pierced with the cold chisel, dropped overboard, and thrust under the surface with the boat-hook; and we return to port. Assuming unpaid labour and that the boat is let with the house, costs are negligible and more than offset by increased output of lake fishes.

It is proposed to set up two expert advisory committees, one to report on the best methods of muffling oars, for night work, and one to consider and recommend methods of disposal of Chianti flagons, having regard to the fact that, as they come from Italy, the rebate of 30 centimes given on Swiss wine-bottles is not payable, and they are too attractive to dump in the lake.

Norwich

d by Tietz et al. My technique in producing and naging the electronarcosis is much the same as that cribed by the above workers, and I can only suppose t the difference in the result must be due to the fact t my electrodes are larger. I use the standard electrodes from the Caplan Electroconvulsant Apparatus, ich are made of aluminium and measure 3 in. × 2½ in.; se are placed in the middle of the temples.

Apart from the differences in current density, variation electrode area would appear to lead to stimulation different parts of the brain. Tietz et al., who use trodes measuring 1·5 in. × 2 in., describe the effect of nges in their placement on the type of electronarcosis duced by a similar current. Their usual placement is in. in front of the mastoid, but if stridor develops at ow current level they move the electrodes forwards 3-3½ in., and if the secondary rise of current to mA does not result in a satisfactory narcosis they ve them backwards. Large electrodes such as I use er most of these areas simultaneously, and as regards nesia and the depth of the postnarcotic unconsciouss this would appear to be an advantage. I have not perienced any real difficulty in producing an adequate ctronarcosis in most cases, and I have been impressed the fact that sometimes it has not been necessary to se the secondary current above 80–90 mA.

An obvious difficulty which confronts any investigation the effects of variation in the electrode size and acement is that patients' heads differ in both size and ape, so that satisfactory contact with equal areas of in in corresponding positions is hard to obtain, and if tainable it bears little relation to the anatomy of the derlying cerebral cortex in the different patients. evertheless I feel that the above observations point to field for further investigation which may prove fruitful.

London, W.1. GERALD CAPLAN.

CRAMP AND SALT BALANCE

SIR,—I read with great interest Sir Arthur Hall's aper of Aug. 16 on cramp and salt depletion. My perience is similar to Dr. Gavin Thurston's which he escribes in his letter of Aug. 23. I agree that salt, though worth trying, is usually disappointing. It is so certain that intermittent claudication does not predispose to cramp at rest or during sleep.

Tobacco was clearly the cause of nocturnal cramps n a man I treated some years ago. I have good reason o remember him, for he was my first patient, though e never knew it, and I have not since given more uccessful advice.

He was a vigorous man of 58 who played tennis and hunted ithout any trace of cramp. He came to me because of octurnal cramps from which he had suffered for a few weeks nd which were increasing rapidly in frequency and severity. It seemed that the act of falling asleep was a trigger for his ramp, and he dreaded going to bed. Finding no defect in is nervous and vascular systems, I temporised, and to egain my composure offered him a cigarette. This made him sk, by the way, if there was any harm in smoking 70 cigarettes a day. I seized upon his suggestion and advised him to restrict his smoking. He was that rare bird, the patient who believes that the doctor's advice should be tried. He gave up smoking and never had another cramp.

London, W.1. L. P. E. LAURENT.

SIR,—In the first place I should like to thank Dr. Thurston for his interesting case-report in your issue of Aug. 23. Since then I have also received a private letter from an officer of the R.A.M.C. which illustrates so strikingly the occasional occurrence of a fulminant attack of cramp in ordinary life, comparable to that seen in the miner in hot seams, that, with his permission, and in his own graphic words, I wish to record it. He has been an athlete all his life, and never suffered from cramp even after the most violent exercise in all sorts of climates, except as hereunder:

‘During the retreat from France in 1940, at the age of 48, in a physically very fit state, I was on the beach at Dunkirk for 5 days in May. It was hot, fine weather; we had reached the Dunkirk area after a very strenuous three weeks, water was very short and food difficult to obtain, so that I had been on short rations of both for nearly a week. On the third evening we were badly strafed from the air. I had retired to a ‘grave’ which I had made myself in the sand about 2 feet deep; lying in this ‘grave’ whilst the strafing was on, I heard a cry for help near by. I made a sudden movement to struggle to my feet and was at once smitten with the most acute cramps in my arms, legs, belly, and shoulders. The pain was very severe and it took me several moments before I could raise myself from the sand ‘grave’ and even then was almost incapable of movement. After about 3 minutes the acute pain worked off, but all my muscles were very stiff and sore. I reached the dressing-station after collecting the casualty, and found some cooking salt and a very small quantity of water; making a strong mixture I drank it and almost made myself sick in the effort. However, the effect was remarkable and rapid, for in about ten minutes all symptoms of the cramp had gone and the stiffness of the muscles had almost completely disappeared.”

It is reasonable to assume that the factor which determined this fulminant attack of cramp in a man previously “cramp-free,” even in active athletics in hot climates, was the insufficient intake of salt during the previous week or so of diminished food and water rations.

Sheffield. ARTHUR J. HALL.

POLIOMYELITIS

SIR,—The following clinical observations of the eye in early acute poliomyelitis may be of interest in the diagnosis of the disease in the present epidemic.

What might be called a “prefixation tremor” of the eyes has been noted in three of our cases. When an attempt is made to focus the vision on some object directly in front or slightly to the side, the eyes oscillate two or three times very rapidly before the gaze is finally fixed in the required line of vision.

CASE 1.—A girl of 4 years was admitted complaining of headache and being generally off colour. Apart from a temperature of 102°F I noted only one abnormal physical sign. This was the “prefixation tremor” described above. The following day, as the temperature fell, a flaccid paralysis appeared in both legs and the eye tremor meanwhile disappeared.

CASE 2.—A boy of 7 years was admitted with complaints of headache and vomiting. Apart from a temperature of 101°F, again the only abnormal physical sign was this “prefixation tremor” of the eyes. A diagnostic lumbar puncture showed 14 lymphocytes per c.mm. in the cerebrospinal fluid, and two days later paralysis developed in the right leg. With the onset of the paralysis and fall of temperature the eye tremor disappeared.

CASE 3.—A boy of 5 years was admitted having suddenly developed left arm paralysis. The temperature rose to 101°F and the “prefixation tremor” appeared in the eyes. The pyrexia and eye tremor lasted until the paralysis spread to the other limbs, gradually decreasing as the paralysis became more pronounced.

I wish to emphasise that in none of these cases was there any nystagmus and I wonder whether this sign, so striking when once seen, can be regarded as pathognomonic of early acute poliomyelitis.

BASIL STRICKLAND.

Victoria Hospital for Children, Tite Street, London, S.W.3.

SIR,—I have recently used a form of treatment in the very early stages which appears to be promising. It is to apply heat to the involved muscles twice a day by short-wave diathermy.

The muscles most often attacked in poliomyelitis are those which become fatigued—for example, the deltoid muscles in the upper extremity, the tibialis anticus in the legs, the short extensors of the wrist, and sometimes the pronator teres in tennis-players. This fatigue factor led me to think there might be some local condition in the muscle, such as excess of lactic acid or other metabolites, which rendered it susceptible to the action of the virus. Supporting evidence is the frequent history of exercise followed by a bathe: the cold water would tend to decrease elimination of metabolites, and the muscles would thus be made more susceptible. I have often been struck by the extensive involvement in cases with this history of bathing.

Letters to the Editor

BEDS

SIR,—Your leading article of Aug. 9 draws attention once again to two methods by which, to some extent, the ever-growing pressure on the general hospital wards might be reduced. There is no doubt that this is the time when those interested in the future of our hospital service should be carefully considering all suggestions of this sort. If in fact the nation takes over all hospitals in the country during the course of 1948 there will be many opportunities of putting these suggestions into practice. In Plymouth, for instance, the two large hospitals, municipal and voluntary, which stand literally side by side, will form a group of buildings which must be reorganised as a single institution. This will give an opportunity of revising completely the present allotment of wards; and, at the same time, it is a virtual certainty that the conditions of work of the hospital staff will be put on an entirely new footing.

A regular travelling consultant service for all major departments will be a comparatively obvious and simple thing to organise. The cottage hospitals in the surrounding district could be visited regularly by consultants, who will take with them a clerk, possibly a clinical assistant, and a technician for any special apparatus they may require. Such a scheme would provide a vastly better service for patients in a scattered rural district like Devon and Cornwall, and would enable the consultant to do far more work with greater efficiency. At present a great deal of their time is occupied in long-distance motoring, usually to see one, or at most two, patients on each journey.

You also draw attention to suggestions which have been made in the past that hostels should be arranged in which patients could stay for short-term investigations. The idea has the double object of providing more convenient service for patients themselves and relieving pressure on the general wards and their overworked nursing staff. The hostel could of course be served by a much less elaborate staff than a general ward. Prof. L. J. Witts advocated a modification of this idea in his article, Length of Stay in Hospital, published a year ago.[1] He favoured the view advocated by Sir Ernest Rock Carling and put into practice at the Westminster Hospital. Here, instead of the hospital being organised on the old plan with a large separate outpatient department, it is constructed of a number of floors or wings each allotted to a medical or surgical unit and comprising a diagnostic and treatment block corresponding with our present general ward, a short-stay ward or hostel, and a long-stay ward. The outpatient department of the unit would be on the same floor, and all sections would come under a single team of doctors, nurses, technicians, and assistants. Such a scheme obviously holds out many advantages. It would be particularly convenient and valuable if, under a new régime, the senior staff concentrated all their work at the hospital, and the present system of having private consulting-rooms in other parts of the town were abandoned. I can foresee that the greatest difficulty in its execution is likely to be the dearth of building facilities, for it would entail a drastic modification of the general layout of most of our large hospitals. However, if the scheme is accepted as the ideal and as the ultimate objective to which we should work, then as from time to time opportunities for building and for reorganisation arise, as we must surely hope they will, they can be used in that direction.

Hospital management committees will shortly be constituted all over the country. Now is the time when such ideas should be carefully thought out and discussed, so that we may have clear and progressive suggestions to lay before these committees when they come to their duties with fresh and unprejudiced minds, and when our hospitals are in the plastic state of reorganisation and capable of being more easily moulded on broad and wise lines.

Plymouth. W. A. LISTER.

H. INFLUENZÆ MENINGITIS

SIR,—The encouraging results in the treatment of *Hæmophilus influenzæ* meningitis with massive doses of penicillin and sulphadiazine, recorded in your issue of Aug. 2, prompt the following brief report of 2 cases in infants. These demonstrate the importance of early diagnosis and treatment, for in both the infection was soon brought under control yet death occurred from hydrocephalus.

1.—A.B., aged 15 months. Admitted in coma to the Royal Hospital, Wolverhampton, on April 18 after nearly 3 weeks' illness. The cerebrospinal fluid (C.S.F.) contained 2000 polymorphs per c.mm., no sugar, and numerous organisms shown to be *H. influenzæ*. Treatment with daily intrathecal penicillin, 100,000 units of penicillin 3-hourly by intramuscular injection, and intravenous sulphadiazine was started. The organism was found to be inhibited by 10 units of penicillin per c.cm. and the C.S.F. was sterile by April 21. On the 22nd a block became manifest; ventricular puncture was done and an excess of slightly turbid but sterile fluid was removed. This was repeated thrice more, the fluid remaining sterile, and on the 25th lumbar taps again became productive. The temperature settled on the 28th. A total of 10 million units of penicillin and 47 grammes of sulphadiazine was given. The child never became fully conscious, his limbs remaining rigid, and the most he was able to do was to swallow fluids. He died on Aug. 6 after contracting measles.

Necropsy showed a communicating hydrocephalus with gross dilatation of the lateral ventricles.

2.—C.D., aged 4 months. Admitted to the Royal Hospital on July 11 after 15 days' illness. She had had convulsions for 11 days. Lumbar puncture produced no fluid but cisternal puncture yielded a few cubic centimetres of turbid fluid containing scanty *H. influenzæ*. 50 c.cm. of purulent fluid were removed by ventricular puncture; 50,000 units of crystalline penicillin were introduced, and parenteral penicillin was started. Intravenous sulphadiazine was also given. Ventricular tap was repeated and by July 15 the C.S.F. was sterile and was obtained from the lumbar route. A concentration of 4 units of penicillin per c.cm. was obtained in the fluid and the temperature settled on this date. Block developed again on the 21st, but the ventricular fluid was still sterile. Thereafter the course of the disease was similar to that run by the first case and the child died on Aug. 3 after a fortnight's generalised spasticity. She received a total of $2^1/_2$ million units of penicillin parenterally, intrathecal and intraventricular penicillin for 10 days, and 25 g. of sulphadiazine.

Necropsy findings were almost identical with those of the other case.

Wolverhampton. H. EVERLEY JONES.

ELECTRONARCOSIS

SIR,—In your issue of Aug. 9 (p. 198) Paterson and Milligan describe in a very clear manner the technique of electronarcosis. I have had some experience with this new method of treatment recently, and the following point is of interest.

Tietz et al.[1] mention that some of their patients had an inadequate amnesia for the period of treatment, and I understand that workers in this country who have used the Shotter-Rich apparatus have also been troubled by this complication. For the patient this is a terrifying possibility since it means that he remains at least partially conscious during a period of paralysis and respiratory embarrassment. I have myself not encountered this complication, and on the contrary I have been impressed by the deeply unconscious state of my patients under treatment. The recovery phase has been longer and quieter than with electrical convulsion therapy, and this period is usually included in the amnesia. Because of this most patients who have had both treatments prefer electronarcosis, since it is the memory of the postconvulsive stage of restlessness and confusion which is largely responsible for the fear of electrical convulsion therapy which sometimes develops.

My apparatus, which was designed in coöperation with Mr. Oswald Sneath, B.SC., is a lightweight instrument with a non-thermionic current control circuit. It resembles that described by Paterson and Milligan, and its output is similar to the Plesset apparatus, which is ults. While these findings are naturally subject confirmation or the reverse, our limited experience ds us to suggest that the undoubted analgesic pro- rties of miadone will find it a place in fields other than se of obstetrical analgesia.

ASHRIDGE

SIR,—While fully endorsing the remarks in your notation last week, I should like to commend the hridge "weekend habit" to medical men. In the nfortable atmosphere of a house-party one can spend o days in the consideration of various topics of national portance under the guidance of experts. It provides cellent opportunities both for informal discussions and learning to speak in public. All opinions are welcome d the Ashridge College is not now linked with any litical party.

JOAH BATES.

POSTGRADUATE TEACHING IN OBSTETRICS

SIR,—I read with great interest your Students' Guide the issue of Aug. 30, and feel sure that this will be a ry great help both to students and to postgraduates. t the same time I was rather surprised and most sappointed that the Combined Postgraduate Teaching hool in Obstetrics and Gynæcology of Queen Charlotte's d Chelsea Hospital for Women was not mentioned. his school is running refresher courses and courses for e M.R.C.O.G. and D.R.C.O.G., the deans being Mr. G. E. Arthure, F.R.C.S., of Queen Charlotte's and r. C. D. Read, F.R.C.O.G., of Chelsea Hospital, with teaching staff outstanding either in obstetrics or in næcology. The school is recognised by the University London and the Postgraduate Medical Federation. urther particulars can be obtained from Miss M. E. aylor, secretary, The Combined School, Chelsea Hospital r Women, Dovehouse Street, S.W.3.

A. J. ESPLEY
Vice chairman.
Hellingly, E. Sussex.

ÆTIOLOGY OF INFANTILE ENTERITIS

SIR,—Your leader of Aug. 23 on the epidemiology f infantile enteritis was welcome, in particular your lea for renewed and more extensive epidemiological tudy. It is my opinion that valuable ætiological informa- ion could be obtained by a combined field survey and aboratory investigation of the nutritional aspects of his disease. In support of this I offer the following aragraphs.

It has been repeatedly found that the main incidence nd fatality of infantile diarrhœa falls on the babes of he poorer sections of our urban populations, while the isease seldom attacks the better-off classes. Largely rom this, it had been concluded that overcrowding and nsanitary conditions of the homes of poor people were esponsible for outbreaks of the disease; the assumption eing that infantile diarrhœa was a bacterial infection of the gastro-intestinal tract and that adverse housing conditions favoured the spread of bacteria.

In an epidemiological survey of infantile diarrhœa in Dublin during 1942 and 1943, my colleague Dr. J. St. L. O'Dea[1] showed that the incidence and fatality of the disease was much the same in the overcrowded slum districts as it was in many newly built well-planned working-class suburbs. The inhabitants of both types of area were of the same income-group (more truthfully, lack of income group), and indeed most of the occupants of the new houses had come from the slum areas. Undoubtedly the slum houses, the "tenements" of Dublin, are overcrowded and often insanitary, but this cannot be said of the houses in the new suburbs. Overcrowding and insanitary conditions are therefore not necessarily associated with the disease, and some other accompaniment of poverty must be concerned. It is probable that malnutrition plays an important rôle. In a survey of the disease in Holland in 1945, Van Creveld[2] agreed with this view.

Again, field-surveys have shown that breast-fed infants, even of the poorer classes, tended to escape the disease while the artificially fed had a high incidence. It has been tacitly accepted by some that the protective mechanism of breast-feeding is due to the transfer of bacteria-free milk directly to the infant, and that the high incidence among the artificially fed is related to the contamination of cow's milk by pathogenic or facultatively pathogenic bacteria. It is now known that maternal milk is commonly contaminated with bacteria, particularly staphylococci. Moreover O'Dea[1] could find no difference in incidence or fatality by dividing the artificially fed diarrhœal infants into two groups—those fed on loose "raw" milk, and those consuming high-grade bottled milk. This does not support the theory that contaminated milk is the source of the disease, nor could I incriminate any bacteria isolated from a number of milk samples.[3] Does human milk contain an anti-diarrhœal factor absent from cow's milk? Or is the general level of the infants' nutrition mainly concerned?

Further support that nutritional factors play a part in the causation of infantile diarrhœa comes from autopsy and liver biopsy material. I found[4] that the livers of infants dying of gastroenteritis showed various degrees of degeneration including fatty change and accumulation or deposition of the brown non-iron-containing pigment in and between the liver cells. Similar changes were reported by Debré[5] in France, in the livers of infantile pellagrins in South Africa by Gillman and Gillman,[6] and in the tropical nutritional deficiency called kwashiorkor by various writers.[7]

Bacteriological studies have shown that no common pathogen exists; although in most epidemics various non-lactose-fermenting gram-negative bacilli were isolated, including *B. proteus*, *B. morgani*, various types of paracolon bacilli, and in a minority of cases organisms of the dysentery and salmonella groups. In other outbreaks no incriminatory organisms were found and a virus infection was postulated.

In 1943 I carried out experiments with young kittens in an attempt to reproduce the disease by the oral administration of paracolon bacilli freshly isolated from the fæces of infants suffering from gastroenteritis. Partial success was achieved, particularly with type-A paracolon strains.[3] At necropsy the successfully infected animals showed pathological findings similar to those found in human cases. But this feline diarrhœa could not always be produced even with a "kitten-passaged" paracolon strain. Too many kittens were resistant and the results suggested that another factor was involved. As the epidemiological and some of the pathological findings pointed to nutrition, an experiment (unpublished) was later performed to test the combined effect of malnutrition with infection.

Twenty-four kittens, 3–5 weeks old and weighing 8–16 oz., were divided into four groups of six animals (A, B, C, and D). A and B were fed adequately with cow's milk and increased satisfactorily in weight over a test period of two weeks. C and D were fed with diluted skimmed milk in such quantities that they put on very little weight over the same test period. Then the kittens of B and D groups were given 1 c.cm. of an overnight broth culture of a paracolon type A strain.[3] Diarrhœa occurred in three groups of animals B, C, and D whilst all the A animals (controls) remained well. Two B kittens (well fed, infected) developed diarrhœa and one died; one C kitten (semi-starved, not infected) developed diarrhœa but survived: while five of the D animals (semi-starved *and* infected) went down with severe diarrhœa and three of these died.

This experiment, although carried out with few animals, supports the hypothesis that the previous nutritional state is important in determining how many

The only way I could discover of getting rid of these products was by increasing the blood-supply to the muscle, and heat seems to be the only means of doing this. Hot packs might do it, and this may explain some of the successes claimed by Sister Kenny in the early stages; but hot packs also heat up the skin and dilate superficial vessels. Diathermy, which heats up the muscles themselves, should be more effective.

I had the opportunity of treating a case at the Norfolk and Norwich Hospital 11 weeks ago. The acute stage was severe, with a temperature of 103°F, head-retraction, and early paralysis of the abdominals and the whole of the right leg. This continued until the fifth day when I saw the patient for the first time. The right leg and abdominal muscles were then completely paralysed and since the previous day there had been well-marked weakness of the left leg. The right sternomastoid was completely paralysed.

Short-wave diathermy was given twice a day and there was some immediate improvement, which was not dramatic except in the case of the right sternomastoid muscle. This muscle recovered completely next day, and the muscles of the left leg recovered much of their power, though the psoas is still so weak that it will not yet act against gravity. The right leg was also treated, and a flicker of movement returned in the extensors of the toes, the peroneals, and quadriceps.

I recognise how difficult it is to assess any form of treatment in this disease; but my experience of this one case, and of previous cases untreated, leads me to think the method worth trying on a larger scale in the present epidemic. In this particular case the progress of paralysis was rapid before the short-wave diathermy was started, and ceased immediately when it was given. The muscles which had been affected for only a few hours recovered to a surprising extent; but short-wave diathermy is probably not of any use later than a few hours after the onset of the paralysis.

Norwich. G. K. McKEE.

*** In testing this treatment it is well to be sure of the diagnosis. It would be inadvisable, in particular, to use diathermy in a case of acute peripheral neuritis or other condition with sensory changes.—ED.L.

SIR,—In your informative leading article of Aug. 23 no mention was made of the use of penicillin in cases of poliomyelitis complicated by respiratory paralysis. Of those requiring treatment in the iron lung many die from aspiration bronchopneumonia, despite adequate suction drainage of pharyngeal secretions. In hospitals in the Middle East parenteral penicillin became the routine procedure for prophylaxis and treatment of such infections, and this therapy often proved effective in tiding men through the acute paralytic stage of their illness.

London, W.1. GEOFFREY KONSTAM.

SIR,—According to your report of a recent meeting of medical officers of health (Aug. 23, p. 298) there is no evidence that flies are spreading infection in the present outbreak of poliomyelitis. This is so opposed to American experience that I was not surprised to learn from the Ministry of Health that it is essentially an assumption, not based on specific investigations. American research[1] has shown that the virus can be recovered from houseflies and blowflies trapped in urban and rural areas during poliomyelitis outbreaks. Food contaminated by such flies was found to produce the disease when fed to chimpanzees.[2] The flies almost certainly acquire the virus from the stools of poliomyelitis patients or carriers. The virus has been recovered from the stools of a child 123 days after an abortive attack,[3] though three weeks appears to be the average time of persistence.[4] Such an experienced researcher as Sabin inclines to the view that flies are a more important vector than droplets during poliomyelitis epidemics.

One objection to applying the fly-carrier theory to the present epidemic is the apparent lack of opportunity for flies to settle on infected stools. Though the virus has been detected in sewage the dilutions involved seem to be too great for sewage-farms and rivers to be important centres of virus pick-up. Earth-closets are mainly restricted to rural areas, and most of the cases are reported from towns. There is, however, one source of fresh human stools open to visitation by flies embracing every town—our vast network of railway lines. Because of the primitive sanitation on our trains, and the large number of apparently healthy people who may be poliomyelitis carriers, railway tracks may be an important source of the virus. From them flies may contaminate food in nearby warehouses, restaurants, and homes. This might account for the widely scattered outbreaks of the disease and the speed with which it travels both here and in America.

CHAPMAN PINCHER

London, E.C.4. Science Correspondent, *Daily Express*.

SIR,—General agreement on the important part played by excreta in the transmission of the virus in poliomyelitis focuses attention on possible means of dissemination. A factor which so far appears to have escaped notice is the handle of the lavatory chain. Contamination of this familiar and seemingly innocent object is inevitable. Washing the hands after visiting the toilet would eliminate the danger; but brief observation in any public convenience will show how completely this elementary precaution is neglected, and human nature being what it is, no amount of propaganda is likely to improve the situation. The provision of a foot-operated flushing mechanism would provide a complete answer.

St. Bartholomew's Hospital,
London, E.C.1. RICHARD TERRY.

MIADONE (PHYSEPTONE) IN OBSTETRICS

SIR,—We read with great interest the preliminary communication on 'Miadone' by Drs. Hewer and Keele (Aug. 23). A few weeks ago, following its possible use as an analgesic in midwifery, we decided to give it a clinical trial at Queen Charlotte's Maternity Hospital and for this purpose were given generous supplies by Messrs. Burroughs Wellcome & Co. Our findings were as follows.

The drug was given to 43 patients; the time at which it was started was approximately that at which pethidine would have been given.

An initial dose of 10 mg. was given to 36 of the cases. Of these, 20 (55%) needed further amounts. A second dose of 10 mg. was enough for 15 of them; 4 needed a third dose; and one was given a fourth dose, totalling 40 mg. (the administration in this case was spread out over twenty-one hours). The remaining 16 (45%) did not need any further amount.

An initial injection of 20 mg. was given to 7 patients and in no case was it necessary to give any more, though gas and air was used in the second stage.

A fair degree of analgesia was usually obtained; it seems that 10 mg. of miadone produces about the same effect as 200 mg. of pethidine and for a somewhat longer time. In some cases a cumulative effect was noted. Euphoria was not noticeable—rather did it appear that the mothers were inclined to be tearful and depressed. Labour was not prolonged by the drug.

Of the 43 infants, 31 (72%) were in good condition and cried spontaneously.

A further 6 infants (14%) were rather limp and sleepy at birth; 2 were given oxygen and CO_2. Of this group, 2 of the mothers had a total dosage of 30 mg. of miadone, 2 had 20 mg., and 2 had 10 mg.

The last group of 6 infants (14%) were classed as being in poor condition and gave rise to some anxiety; 2 showed white asphyxia, and in the other 4, though their colour was reasonably good and their heart-beat strong, respiratory depression lasting for up to an hour was a well-marked feature. All these 6 babies were given oxygen and CO_2; one was also given lobeline and in another case it was necessary to give both lobeline and nikethamide. The total dosages in this group were: 1 mother was given 40 mg., another had 30 mg., 3 had 20 mg., and 1 had only 10 mg.

The factor that appears to be responsible for the ill effect on the child is the total dosage; rather that than the nearness of the last injection to the time of delivery.

It is because of the high incidence of near disasters to the babies that we hasten to communicate these

n his hospital he was just ' the chief '—a beloved figure hom everybody knew was a skilful surgeon, a superb acher, an excellent administrator. But beyond all iat he was just the life and even more the soul of ie place. He continued in harness right up to the very id, and no more gallant fight against quite impossible lds was ever fought. It was no easy task to follow arvey Cushing; but when time in due course evaluates e two men, one feels that, though perhaps in quite a fferent way, Elliott Cutler has done no less for American rgery than his distinguished predecessor.

"Elliott the man has gone; his example, his dreams, s friendship live on in a thousand and one places on oth sides of the Atlantic. He was a man amongst en; his zest for life lives on after him. His passing aves the world a poorer place, but for those who knew m it must always be a richer."

Mrs. Cutler survives him with four sons.

THOMAS JOHN CAREY EVANS

KT., M.C., M.D. BRUX., F.R.C.S.

Sir Thomas Carey Evans, who died on August 25 at ie age of 63, had retired from his post as medical iperintendent at Hammersmith Hospital in 1944. His iends had hoped that he would enjoy some years of uiet retirement on his farm at Criccieth.

Press Portrait Bureau

The son of Dr. R. D. Evans, of Blaenau Festiniog, he udied medicine at Cardiff, in London at St. Bartholomew's Hospital, and in Glasgow. Qualifying in 1905, he held house-appointments and studied abroad before he entered the I.M.S. In 1910 he took his F.R.C.S. and was appointed surgical specialist to the Lucknow division. Soon afterwards he joined a punitive expedition against the Abors, a tribe of head-hunters on the Assam frontier whose young men had recently added the heads of some British officials to their collection. Later he became senior medical officer of the Mishmi party which explored a tract of unknown country between Tibet and the N.E. Frontier of India and mapped art of the unknown course of the Brahmaputra.

During the 1914–18 war Carey Evans accompanied he Indian Expeditionary Force to Egypt. He served hrough the whole of the Gallipoli campaign and was warded the M.C. for gallantry in action. After the vacuation of Gallipoli he was transferred to the lesopotamia Field Force, and in 1917, as civil medical fficer of Bagdad, he had to organise medical relief or the civilian population and do most of the surgery f the town. To add to his difficulties it was a year f exceptionally hot weather and there was a severe utbreak of cholera. Young and energetic, he worked nceasingly under conditions which made a severe call n his courage and physique, and his services were ewarded by a brevet majority, the Legion of Honour, nd three mentions in despatches.

On his return to India he was appointed residency nedical officer to the State of Mysore; in 1921 he was elected to be surgeon to the Viceroy, and in 1924 he was knighted. A few years later he retired from the I.M.S. for the sake of his children's education.

Carey Evans was appointed surgeon to St. Paul's Hospital and to the Hospital for Tropical Diseases and practised for some years in London, till in 1933 he took up the appointment of medical superintendent of Hammersmith Hospital. The British Postgraduate Medical School was to be established in association with this hospital, and it was a fortunate chance for the school that placed Sir Thomas in control of the hospital. Colonel Proctor, to whom we are indebted for much of this memoir, writes: "I had known of Carey Evans in the service mainly by reputation, as a brilliant and promising officer. I had seen him toasted and heard him cheered at I.M.S. dinners, but it was not till we became associated at the British Postgraduate Medical School that I really got to know him. The school opened in 1935 and problems arose in adapting municipal hospital practice to teaching school requirements, but Carey Evans invariably found an amicable solution. Impulsive by nature he would at times react violently to actions of the staff, but these explosions were so genuine and so part of the character of the man that they never left any ill feeling and often cleared the air. First and foremost in his mind was the comfort and welfare of his patients, and next the smooth working with the school.

"The outbreak of war brought the hospital into the Emergency Medical Scheme. As it was situated in a heavily blitzed area, the maintenance of the hospital's efficiency caused him much anxiety. Fearless himself, whenever bombs were falling near he would at once go round the outside of the hospital to make sure his blackout was still complete. Carrying a risk, it was not a duty he would delegate to others. When the Home Guard was formed he was one of the first to join. He would not accept any promotion but attended all parades and exercises, until his youngest son, also a member, took alarm and persuaded him to leave out the more strenuous, as being too severe for a man of his age. Carey Evans always liked people around him and dispensed a generous hospitality to old and young. He was happiest when he had his family at home, and at Hammersmith he kept open house during the war for their friends as well as his own.

"In 1944 he retired from the hospital on the age-limit, and took up farming at Criccieth. He set to work with all his old enthusiasm, and, ably backed by his wife, Lady Olwen Carey Evans, the eldest daughter of the late Lord Lloyd George, in three years had transformed a somewhat neglected place into a modern and efficient farm. I asked him how he had survived the severe winter this year. His answer was characteristic. 'Not too badly! Lost a few lambs but did well with the cattle.' Carey Evans could always see the brighter side of life.

"He loved Wales and was well versed in its early history and literature, and spoke Welsh fluently. On a fishing expedition he would stop for a chat with every one he met, and in a few minutes you saw tinkers, tramps, poachers, labourers, or landed gentry apparently reviving a friendship of years. He was full of good will to all men, and one could not fail to recognise it."

"It is over thirteen years since I first met Carey Evans," writes Prof. Lambert Rogers, "in the early days of the British Postgraduate Medical School when I had the privilege of assisting Professor Grey Turner in organising the surgical work. Sir Thomas, then superintendent of the Hammersmith Hospital, Colonel Proctor the dean, and Captain Scotland the secretary, formed a triumvirate which gave the administrative side of the school a grand beginning. Carey Evans was always most helpful and coöperative, and ever cheerful—I never once saw him put out or in any way depressed—and being a surgeon himself he was highly sympathetic to our problems. He was a friend to us all at a time when the new school was an innovation and something of an experiment, and when those of us who were the first members of its staff were to a certain extent strangers in a strange land."

JOHN WILLIAM HUNTER

M.D. EDIN., B.HY. DURH.

Dr. J. W. Hunter, medical officer of health for Ipswich, died on Aug. 26 at the age of 47. From Dunfermline High School he went to the University of Edinburgh, where he graduated in medicine in 1924, and four years later he took his diploma and degree in hygiene at Durham. From 1926 onwards he held posts in the public-health service at Newcastle-on-Tyne, Norwich, Blackburn, Walsall, Portsmouth, and Kensington. In the last three, as deputy medical officer of health, he built up a reputation as a sound administrator, and in 1937 he became M.O.H. for Ipswich. Under his guidance the municipal hospital was modernised and staffed by consultants from the town, and this work will stand as a among the infected will contract enteritis and how many will escape. In other words a dual conception of the ætiology of infantile diarrhœa arises—malnutrition and infection. The former is the underlying and in general the predisposing *cause: the latter the usual exciting* cause. It may be that the relative rôles played by these factors varies from case to case, but in general both play a part. Malnutrition prepares the soil: infection is the seed. Without one the other is usually inoperative.

I do not know what is the biochemical nature of the malnutrition predisposing to diarrhœa. While I believe that most cases arising in the home can be explained on this dual hypothesis, I am aware that neonatal outbreaks in maternity homes and nursery epidemics are apparent exceptions to this conception of the disease. However, the hypothesis is put forward in the belief that it makes sense of most of the known facts and in the hope that the personnel of some future investigation will include experts in the field of nutrition.

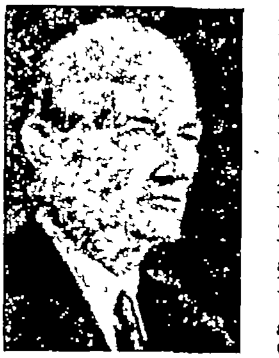
Birmingham Accident Hospital. S. SEVITT.

Obituary

ELLIOTT CARR CUTLER

HON. C.B., M.D. HARVARD, HON. F.R.C.S.

WE have already recorded the death on Aug. 16 of Dr. Elliott C. Cutler, Moseley professor of surgery at Harvard, and surgeon-in-chief of the Peter Bent Brigham Hospital, Boston. He was 59, and the greatest contributions of his later years were made in Europe as chief consultant in surgery, and chief of professional services, in the medical branch of the United States forces. He will be remembered as a fine surgeon, a great teacher, a gay crusader, and a good friend.



The Cutlers are of New England Puritan stock, originally from Norfolk, and latterly they have been noted athletes. Elliott Cutler was captain of the Harvard crew in 1909 and president of the Harvard Alumni Association in 1940. After graduating in 1913 he spent some time in Germany, where (as he related in his Linacre lecture[1]) he acquired a distaste for German manners. After war broke out in 1914 he went to Paris in charge of the first Harvard medical unit, and in 1916 he was commissioned in the British Army. In the following year he rejoined his compatriots, and for his work in forward surgical units, and his able organisation, won the Distinguished Service Medal.

Returning to Harvard as assistant to Harvey Cushing, Cutler became a pioneer of cardiac surgery, and in 1923 was the first to tenotomise the stenosed valves in mitral stenosis, with survival of the patient. His surgical *courage* was *outstanding*, but always based on thought and on experiment. With S. A. Levine and other colleagues at Harvard he introduced total thyroidectomy to relieve heart-failure, and his name is associated with advances in the surgery of the central nervous system, the autonomic nervous system, and the gall-bladder. With R. Zollinger he produced in 1930 an atlas of surgical operations which became a standard guide for the younger surgeons and interns of America. But though he wrote much, his influence was greatest through example and demonstration, and his theme was ever gentleness and respect for the tissues, avoiding hurry and operation by the clock. He taught a rising generation of surgeons the need for thoroughness, and his work at Harvard was, as he put it, to carry on a "school for safety in surgery."

After an interlude of eight years as professor at the Western Reserve Medical School at Cleveland, Ohio, Cutler in 1932 succeeded his old chief, Harvey Cushing, in the Harvard chair. A lieut.-colonel on the reserve, he was called back to active duty in 1942 and came to England with the first wave of U.S. medical units, as chief consulting surgeon. He had many friends *here, some dating from the* previous war, and others who had visited him at his home. But his genius for friendship was such that no introductions would have been necessary. His reputation had preceded him and his place was ready for him in the medical circles of the war, in the consultants' meetings at the War Office, and among his surgical colleagues. His personal attraction, his clear vision, and his enthusiasm always gave him a willing and attentive hearing. He took the initiative in the organisation of the inter-allied conferences on war medicine held at the Royal Society of Medicine, and spared no pains to make them a success. When the war was over he returned to his beloved Boston. The sentence of death which came upon him in the full flood of activity was never allowed to interfere with his plans and he worked to the end.

Mr. A. E. Porritt writes: "The passing of Elliott Cutler, though not unexpected, leaves an acute—almost poignant—sense of loss which for many in this country must be nearly as deep as it is in his native America. As one who was privileged to work in close contact with him during the last three years of the war, to deputise for him for a short period in his chair of surgery at Harvard, and to share in his home life in Boston, I find it difficult to write of him in commonplace phrases.

"For Elliott Cutler was unique in many unique ways. The bare facts of his life and career—his being born of an old New England family which has always lived and still does live in Boston; his brilliance at school and as an undergraduate at Harvard; his part in the first world war as a young medical officer; his rapidly and ever-expanding sphere of surgical influence between the two wars; his invaluable services in the second world war as senior consultant in surgery to the U.S. Army in the European theatre of war, and finally his well deserved acceptance as one of America's leading surgeons in this difficult post-war era, with all the responsibilities and activities such recognition demanded—these, great as each individual phase is if analysed, seem but the background to a personality as dynamic, efficient, and courageous as it was perpetually boyish, friendly, and lovable.

"Elliott must have been a success in any walk of life, not so much because he possessed mental and physical attributes far beyond the ordinary, but because he actively and joyously loved life—all of it. In a front-line operating-tent, at a clinical meeting, sailing his dinghy, 'making rounds' at hospital, in his office, at a dinner-party, he exuded illimitable vitality.

"A man of deep largely unspoken beliefs, he knew he had the gift of making friends—real friends—and to him friendship was almost a religion. His wife was his greatest friend, his children and his family were close seconds, and his home life was a thing of real beauty because of it. His surgical colleagues were his friends; his resident staff were his friends; his patients were his friends; his comrades-in-arms were his friends—and to all and every one of them he gave to the full.

"*In this country during the war, apart* from all he achieved (and only a few in high places know how much that was) for his own service, he did more to foster and advance Anglo-American surgical relationships than any man of his generation. And he did it with that tact, that ease, that dry sense of humour, that clear incisive thought, and always that irresistible energy that endeared him to all with whom he came in contact. He really loved this country and genuinely admired its surgery. One of the wishes closest to his heart was that interchanges in staff between his country and ours should be facilitated and developed to the full. He believed in the youth of both countries and spared no pains to encourage them, and they both trusted him and loved him. No more worthy honorary fellowship of the College of Surgeons was ever awarded than that given to him in 1943.

"In his own country honours—national, surgical, and personal—poured in on him; but innately modest he looked on these as tributes to his work, not to himself.

---

1. *Lancet*, 1944, ii, 427.

pneumonia (primary or influenzal), 233; cerebrospinal fever, 49; poliomyelitis, 626; polioencephalitis, 50; encephalitis lethargica, 1; dysentery, 75; puerperal pyrexia, 150; ophthalmia neonatorum, 79. No case of cholera, plague, or typhus was notified during the week.

Deaths.—In 126 great towns there were no deaths from enteric fever, 1 (0) from scarlet fever, 4 (2) from diphtheria, 5 (0) from measles, 8 (1) from whooping-cough, 61 (10) from diarrhœa and enteritis under two years, and 5 (0) from influenza. The figures in parentheses are those for London itself.

The number of stillbirths notified during the week was 214 (corresponding to a rate of 25 per thousand total births), including 25 in London.

Diary of the Week

SEPT. 7 TO 13

Monday, 8th

ROYAL COLLEGE OF SURGEONS, Lincoln's Inn Fields, W.C.2
3.45 P.M. Dr. L. E. Glynn: Atrophy and Hypertrophy.
5 P.M. Dr. M. Kremer: Concussion.

Tuesday, 9th

ROYAL COLLEGE OF SURGEONS
3.45 P.M. Prof. A. C. Frazer: *Fat Digestion and Absorption.*
5 P.M. Prof. D. F. Cappell: Rhabdomyoma.

Wednesday, 10th

ROYAL COLLEGE OF SURGEONS
3.45 P.M. Prof. John Kirk: Gross Anatomy of the Spinal Cord.
5 P.M. Prof. J. H. Dible: Inflammation, Tissue Reaction, and Repair. (First lecture.)

Thursday, 11th

ROYAL COLLEGE OF SURGEONS
3.45 P.M. Prof. John Beattie: Autonomic Mechanisms of the Brain Stems.
5 P.M. Professor Dible: Inflammation, Tissue Reaction, and Repair. (Second lecture.)

Friday, 12th

ROYAL COLLEGE OF SURGEONS
3.45 P.M. Professor Beattie: Micturition and its Disturbances.
5 P.M. Prof. J. H. Biggart: Pathology of Head Injury.

Births, Marriages, and Deaths

BIRTHS

CURRAN.—On Aug. 26, in London, the wife of Dr. Desmond Curran—a son.

DAVIDSON.—On Aug. 27, at St. Leonards-on-Sea, the wife of Dr. I. E. Davidson—a son.

FULLER.—On Aug. 22, at Colombo, the wife of Surgeon Lieut.-Commander Peter Fuller, R.N.—a daughter.

GILLOTT.—On Aug. 22, in London, to Dr. Ursula M. Gillott (née Bailey), wife of Mr. J. A. Gillott—a son.

HUTCHISON.—On Aug. 28, the wife of Mr. J. B. Hutchison, F.R.C.S.—a son.

POLLARD.—On Aug. 1, at Elburton, the wife of Captain B. R. Pollard, R.A.M.C.—a son.

SARGENT.—On Aug. 22, at Winchester, the wife of Dr. Frank Sargent—a son.

WARBURTON.—On Aug. 20, the wife of Major-General J. R. N. Warburton, late R.A.M.C.—a daughter.

WRIGHT.—On Aug. 22, at Kenilworth, the wife of Dr. E. G. Wright—a daughter.

MARRIAGES

GOUGH—LEE.—On Aug. 26, at Torquay, C. W. C. Gough, major, R.A.M.C., to Clara Lee, major, R.A.M.C.

WATKINS—EVANS.—On Aug. 23, at Glais, Swansea, David Ainsley Watkins, M.R.C.S., to Joy Margaret Evans.

DEATHS

ALLAN.—On Aug. 27, at Wells, Herbert William Allan, O.B.E., M.R.C.S.

BARKAS.—On July 30, at York, Thomas Cook Barkas, O.B.E., M.B. Durh., aged 83.

EVANS.—On Aug. 25, at Criccieth, Sir Thomas John Carey Evans, M.C., M.D. Brux., F.R.C.S.

FULTON.—On Aug. 18, at New Delhi, George Keith Fulton, C.B.E., M.B. Glasg., D.P.H., acting brigadier, R.A.M.C., aged 52

HUNTER.—On Aug. 26, John William Hunter, M.D. Edin., B.HY., D.P.H.

LEMPRIERE.—On Aug. 28, at Ware, Herts, Lancelot Raoul Lempriere, O.B.E., M.B. Manc.

PEAKE.—On Aug. 22, at Bath, Arthur Edward Peake, M.R.C.S.

POCOCK.—On Aug. 21, at Newquay, Herbert Innes Pocock, C.M.G., M.R.C.S., colonel, late R.A.M.C., retired, aged 86.

FILM ON EXANTHEMS.—*Dr. Ronald MacKeith wants to* trace a colour film on the exanthemata which is said to have been shown in England.

Notes and News

RADIOACTIVE ELEMENTS

THE U.S. Atomic Energy Commission has lately released information about the first year's commercial production of radioactive elements by the uranium chain-reacting pile of the Clinton Laboratories at Oak Ridge, Tennessee. 1092 shipments of more than 100 elements were made to scientific and industrial research institutions. Specially labelled, lead-shielded containers allow shipments to be made by road, rail, and air so that there is no hazard to transport staff. Undeveloped photographic film is the only merchandise likely to be affected by long proximity to such a cargo. With isotopes of short half-life, such as radio-potassium (12·4 hours), and radio-gold (2·7 days), specially fast transport is arranged from the laboratories to the customer.

Before the chain-reacting pile was available, radioactive tracer materials were produced in the cyclotron. Here production was limited in quantity and costs were high—for example $1,000,000 per mc. of C^{14} compared with $50 for the same amount now produced in the pile. Even with the vastly increased output of the pile the demand exceeds supply, and distribution is made on the recommendations of an advisory committee which decides priorities. Demands for *medical application get special consideration.*

Therapeutic uses of radioactive phosphorus in polycythæmia vera and leukæmia, and radioactive iodine in hyperthyroidism and some thyroid carcinomas, have already been reported; but it is thought (P. F. Hahn) that only about 9 of the 450-odd known radioactive isotopes will be therapeutically valuable. The main usage therefore of these materials will be as tracers and research tools, enabling investigators to study many physical, chemical, and biological phenomena not fully understood.

MEDICAL DIRECTORY

THE Editor writes: "To maintain the accuracy of our annual volume we rely upon the return of our schedule, which has been posted to each member of the medical profession. Should the schedule have been lost or mislaid we will gladly forward a duplicate upon request. The full names of the doctor should be sent for identification." Applications should be sent to him, c/o J. & A. Churchill, 104, Gloucester Place, London, W.1.

NEW ZEALAND SCHOOL DENTAL SERVICE

EVIDENCE that the condition of New Zealand school-children's teeth has improved tremendously since the introduction of the State school dental service in 1921 was given by Mr. W. B. Tennent, the president, at the New Zealand Dental Association's recent annual meeting at Auckland. When the scheme started, he said, the ratio of extractions to fillings was 114·5 to 100. Now it was 6·3 to 100. At first parents were asked to pay an annual nominal sum for each child, but some years later the service was made free. The government had now extended the free service to include children up to 16 years, the intention being to extend it to 19 years as time and personnel allowed. However, though the number of dental students had risen and today there were 245 at dental school, it would be 20 or 30 years before free dental service could be given to all.

University of Cambridge

Dr. A. M. McFarlan has been appointed to the readership in the new department of human ecology (*Lancet*, 1947, i, 718).

Dr. McFarlan graduated M.B. in the University of Edinburgh in 1935, and in the following year took his M.B. Camb. A senior president of the Royal Medical Society of Edinburgh, he was awarded a Vans Dunlop scholarship in bacteriology in 1935, and later a Walter Dixon scholarship of the British Medical Association. He is a demonstrator in bacteriology at the London School of Hygiene, and during the war was a member of the research teams studying infective hepatitis at the American Red Cross Harvard Field Hospital Unit at Salisbury and later at the Medical Research Council's laboratory at Cambridge.

University of Leeds

Dr. T. A. Divine has been appointed senior administrative officer of the medical school.

Dr. Divine, who is the son of the late Dr. Thomas Divine of Fartown, graduated M.B. at the *University of Leeds in 1033*, afterwards joining the Malayan Medical Service. During the war he was a prisoner-of-war in Singapore and lately he has been an assistant in a general practice in Worcester.

memorial to him for many years to come. During the war his organisation of the medical side of civil defence won the admiration of his council; it is said in Ipswich that John Hunter attended every "incident" and directed the medical services on the spot. He was also chairman of the local medical war committee. In the Society of Medical Officers of Health he was an energetic and successful secretary of the Eastern branch, and he was on the council both of the society and of the Royal Sanitary Institute.

"It was only necessary to know Hunter to like him," writes J. F. "All those under whom he worked were impressed by his loyalty. He had a kindly nature and did much to help those subordinate to himself. Indeed, to them he regarded himself as a friend, with all the obligations which that word connotes. He endeavoured to find good in everybody and was one of those few men who have no enemies." Dr. Hunter leaves a widow and two sons.

HENRY LAING GORDON

M.A. EDIN.

Dr. H. L. Gordon, who died at Ngong in Kenya on Aug. 10, will be remembered for his laborious work on the mental capacity of East African tribes and for his appeal for coöperative research into the causes of native backwardness.

He was born at Penrith in Cumberland in 1865, of Scottish descent, and he qualified at Edinburgh University in 1889. A serious illness made it necessary for him to live abroad and for many years he practised in Italy, South Africa, and Portugal. For some time after the 1914–18 war he was physician to the London Neurological Clinic, mental specialist to the Ministry of Pensions, and assistant at the West End Hospital for Nervous Diseases.

In 1925, at the age of 60, he was attracted by reports of Kenya to take up a medical farm at Koru, which he described as "a very interesting and very unsuccessful experiment." Some three years later he moved to Nairobi, where he set up in consultant practice as a neurologist. During most of this period he was visiting physician to Mathari Hospital; where he was responsible for far-reaching improvements in the buildings and in the methods of treatment, transforming an almost medieval lunatic asylum into a modern mental hospital.

In his retirement at Ngong he maintained the closest association with his profession, and at the age of 80 he read to the Kenya branch of the British Medical Association a constructive paper on Social Reform in Kenya. He was founder-member and member of council of the British Balneological and Climatological Society, a fellow of the Society for Study of Inebriety, and a member of the consultative council of the Eugenics Society.

With Dr. F. W. Vint, he conducted research into mental deficiency in the East African native and on nervous and mental diseases due to syphilis or yaws, which was the background of the memorandum, A Research Required in Kenya, which he presented to Lord Hailey in 1937.

Appointments

BROWN, J. D., M.B. Aberd., D.M.R.: radiologist, Dudley Road Hospital, Birmingham.

GRACE, R. F. T., M.D. Edin., M.R.C.P.: physician i.c. department of psychological medicine, Miller General Hospital, Greenwich.

Manchester Royal Infirmary:
- CHARNLEY, JOHN, M.B. Manc., F.R.C.S.: asst. orthopædic surgeon.
- GRIFFITHS, D. L., M.B.E., B.SC., M.B. Manc., F.R.C.S.: asst. orthopædic surgeon.
- SIMMONS, H. T., B.SC., M.D. Manc., F.R.C.S.: asst. surgeon.
- WILKINSON, J. F., M.SC., M.D. Manc., F.R.C.P.: physician i.c. department of hæmatology.

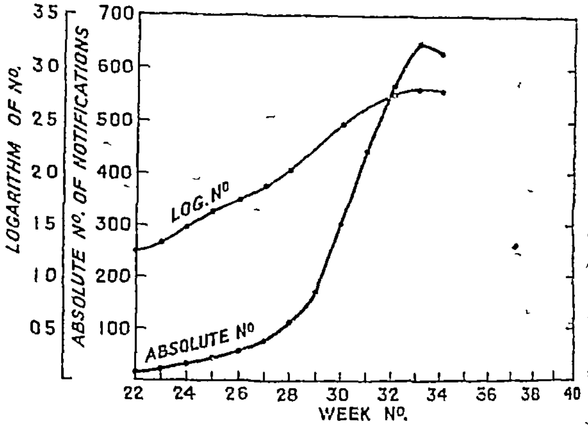
Hull Royal Infirmary:
- BLACKBURNE, J. R., M.B. Lond., F.R.C.S.: surgeon.
- WALTON, PETER, M.B. Edin., F.R.C.S.E.: asst. surgeon.

Colonial Service:
- KIRKALDY-WILLIS, W. H., M.B. Camb., F.R.C.S.E.: M.O., Kenya.
- PITCHFORD, R. J., M.R.C.S.: M.O., Tanganyika Territory.
- SLOMINSKI, J. Z., M.B. Polish School of Medicine: M.O., Windward Islands.
- SMITH, J. F., M.B. Glasg.: M.O., Uganda.

Public Health

Poliomyelitis and Polioencephalitis

THE notifications of poliomyelitis in England and Wales during the week ended Aug. 23 numbered 626. This is a slight reduction on the previous week (640). The Ministry of Health takes the view that the weekly figures may continue to be of a similar order for many weeks, or possibly for several months, and that the decline in prevalence which is to be anticipated with the approach of winter will not be as rapid as the rise which occurred in June and July.



Figures for the various areas compared with those for the previous week (given in parentheses) show that only London 115 (89) recorded a considerable increase. In Durham 33 (39), Lancashire 65 (71), Middlesex 36 (32), Surrey 26 (39), Warwick 26 (37), Yorks, West Riding 49 (44), and East Riding 11 (18) the changes appear to indicate a general tendency either to a temporary stability or the beginning of a decline.

There were 50 notifications of polioencephalitis, a figure of the same order as for the two preceding weeks (45 and 56).

In the last few weeks, though the upward trend in the absolute numbers of weekly notifications of poliomyelitis continued, a hopeful sign was the persistent decline in the rate at which these absolute figures were mounting. In the weeks ended Aug. 2, 9, and 16 the totals were 48%, 27%, and 14% of the total in the preceding weeks. Epidemic curves of the present type tend very roughly to follow the hump-shaped form of the "normal" frequency distribution whose peak occurs when this proportionate increase becomes zero. In practice, the trend of this rate of change can best be watched by plotting (as in the figure) the *logarithms* of the numbers of notified cases in consecutive weeks. The vertical distance between two points on this logarithmic scale—i.e., the difference between their logarithms—represents the ratio of one number to another and indicates the size of the proportionate increase. A consistent rate of increase (as in the 22nd to the 29th week) is indicated by a series of equal upward steps which can be joined to form a straight line. At the 31st week, however, this steady upward trend changed and a flattening logarithmic curve indicated a slowing down of the rate of increase. There is as yet no mathematical certainty in epidemiological prediction, but the rapid fall in the rate of increase to a value near zero in the 31st to 33rd weeks suggested that, at least in the present phase, the tide was about to turn.

The total for the week ended Aug. 23 for the first time shows an actual decline, and the fact that this follows the trend of the preceding weeks suggests that the fall will continue, but the Ministry's cautious view is no doubt based on the recollection that September has in the past been a month of high prevalence.

Infectious Disease in England and Wales

WEEK ENDED AUG. 23

Notifications.—Smallpox, 0; scarlet fever, 489; whooping-cough, 1818; diphtheria, 147; paratyphoid, 23; typhoid, 12; measles (excluding rubella), 3278;

RESULTS

Fig. 1 shows the typical changes of the serum-protein picture and of colloid pressure in the sera of our patients during the experiments. Our present data confirm Podhradszky's (1940a) statement that in diabetes insipidus the water-binding activity of serum-proteins often decreases, and so the reduced colloid pressure is lower than normal, if the patient is allowed to drink freely. During the period of thirst the level of serum-proteins and their water-binding activity—i.e., the reduced colloid pressure of the serum-proteins—increase. At the same time a fall in the A/G ratio indicates an increase in the amount of globulins. Thus, parallel to simple concentration, the qualitative and quantitative protein picture changes, and this, according to Podhradszky (1940a and b, 1942a and b), is probably the result of regulation by endocrines.

The increased amount and activity of the proteins lead to a rise of about 100 mm. H_2O in the absolute colloid pressure. Fig. 2 shows the reduced colloid pressures observed in cases of diabetes insipidus during drinking (unrestricted water intake) and thirsting conditions. All values obtained when drinking was unrestricted lie below the line representing the physiological correlation between albumin concentration and reduced colloid pressure, which means that the water-binding activity of the proteins was less than normal. When water intake was severely restricted, the reduced colloid pressure of the same patients reached or approached the line of physiological values, indicating an increased water-binding activity of the proteins. The A/G ratio—shown in numerals at both ends of the arrows indicating change in reduced pressure—fell in each case.

Fig. 3 illustrates the glomerular and tubular functions of the kidney in our patients under the changes of colloid pressure described above.

Thirsting Phase.—When the rise in pressure reaches its maximum, both the creatinine and chloride clearances decrease, the chloride more than the creatinine. These changes indicate decreased glomerular function (inhibited filtration) and increased tubular function (augmented resorption). Thus, reduction of urinary flow is due to changes occurring simultaneously in both the glomerular and the tubular functions, the latter, owing to their larger extent, being the more important. Fig. 3*a* shows the greatest rise in pressure and greatest reduction of urine flow. This fact speaks for a proportional correlation between colloid pressure and kidney function.

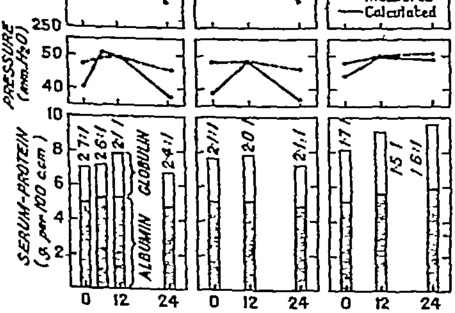


Fig. 1—Changes in serum-colloid pressure in diabetes insipidus during thirsting and drinking phases (3 experiments). Upper charts show total colloid pressure by measurement and by calculation. Lower charts show "reduced pressures"—i.e., colloid pressure which would be exerted if serum-protein were reduced to a standard level of 1%. Lower charts also show actual serum-protein values and albumin/globulin ratio.

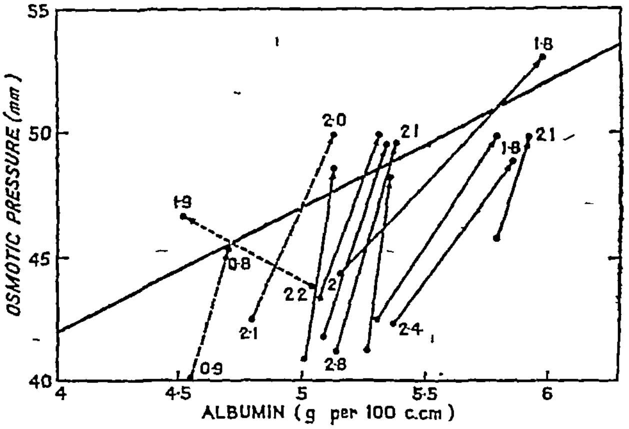

Fig. 2—Variations in "reduced" colloid pressure in diabetes insipidus on changing from drinking to thirsting phase (unbroken arrows). Continuous line represents calculated correlation between pressure and albumin level in serum. In the drinking phase all values are low, showing that water-binding power of the proteins is less than normal. Numerals at ends of lines indicate albumin/globulin ratio. Broken arrows show effect of posterior pituitary extract instead of water restriction.

Drinking Phase.—Decreased colloid pressure is accompanied by increased clearance of creatinine and chloride, the creatinine indicating increased glomerular function (augmented filtration) and the chloride decreased tubular function (inhibited resorption). Thus augmentation of urinary flow is due again to changes occurring simultaneously in both the glomerular and the tubular functions. Fig. 3*b* shows a relatively greater drop in pressure and increase of urinary flow than fig. 3*a*, and this again denotes correlation between colloid pressure and kidney function.

In the experiment shown in fig. 3*c* the protein picture of the serum during the drinking phase did not return to its original state, and consequently the absolute colloid pressure also remained high (see fig. 1*c*). Neither glomerular nor tubular function in this state returns to the original level (figs. 3*a* and 3*b*), but filtration remains inhibited and resorption increased. Accordingly, urine flow does not reach the original high value, in spite of the fact that the patient has been allowed to drink without restriction.

DISCUSSION

Our present work confirms Podhradszky's (1939) results. He then showed that in diabetes insipidus, if the patient is allowed to drink as much as he wants, the water-binding activity of the serum-proteins is much less than in a healthy person. Consequently the reduced colloid pressure of the serum is lower than normal, as in other "hypofunctional" endocrine diseases. The activity of these proteins increases, and the colloid pressure rises, if the water intake is strictly restricted. Identical results are obtained if, instead of water restriction, extracts of posterior pituitary are administered (fig. 2).

Our investigations also show that both glomerular and tubular kidney functions follow the changes in the colloid pressure of the serum closely and regularly. If the pressure rises, filtration in the glomeruli decreases, whereas resorption in the tubules increases; these two parallel changes lead to a diminution of urinary flow. If the pressure drops, filtration in the glomeruli increases and resorption in the tubules decreases; these two parallel changes thus lead to an increase of urinary flow. These results, besides confirming Podhradszky's (1939) experimented, other show that changes in the colloid pressure may infl pethidine in thubular but also glomerular function.

Inion faded away, e results we have to answer two [illegible] apparent benefit [illegible] pressure of the [illegible] an

Though no evidence has been obtained of any increase in toxicity when BAL is injected into animals with experimentally induced renal damage, or of renal irritation in any of the cases of this series, increased toxic effects were present in animals with hepatic damage, which suggests that care should be exercised in the administration of BAL to patients with impaired liver function (Cameron et al. 1947). It should be added that BAL is not generally indicated in the treatment of post-arsphenamine hepatitis, the immediate cause of which appears to be infective in most cases (Salaman et al. 1944). Local abscesses have developed at the injection sites in some cases treated in this country. These may have been due to the septic condition of the skin in patients with exfoliative dermatitis of some standing, who are, in any case, prone to intercurrent infections of all kinds. This complication is probably preventable by the administration of BAL early in the course of the condition. A possible contributory factor is the leakage of BAL into the subcutaneous tissue, which may be prevented by giving all the injections deep into the muscles. The abscesses, though troublesome, have healed satisfactorily with simple treatment, and do not, in our opinion, constitute a contra-indication to the use of BAL in such cases.

DISTRIBUTION

Up to now BAL has been manufactured by the Ministry of Supply, and, so that its therapeutic value could be firmly assessed, distribution has been effected only through the Medical Research Council. It is considered that the value of the compound has now been established, and arrangements are being made by the Ministry of Supply for the preparation and issue of ampoules of BAL by firms in a position to exercise adequate biological control.

We wish to thank Miss F. B. Uffelmann, of the Ministry of Supply; the various clinicians who have coöperated in this trial; and Messrs. Boots Pure Drug Co. Ltd. and Messrs. Burroughs Wellcome & Co. for dispensing the material used.

KIDNEY FUNCTION IN DIABETES INSIPIDUS

A. GREINER
M.D. Budapest
MEMBER OF STAFF

L. PODHRADSZKY
M.D. Budapest
ASSOCIATE PROFESSOR OF PATHOLOGY

INTERNAL CLINIC, ROYAL HUNGARIAN PETER PAZMANY UNIVERSITY, BUDAPEST

BY creatinine-clearance and chloride-clearance tests on dogs Podhradszky (1939) showed that changes of 30–60 mm. H_2O in the colloid pressure of the serum did not significantly affect the glomerular filtration of the kidney. Tubular function, however, followed these shifts of colloid pressure very precisely—i.e., its rise was connected with increased reabsorption (lessened flow of urine) and its diminution with decreased reabsorption (increased flow of urine).

The results of these incomplete though promising experiments encouraged us to investigate kidney function in diabetes insipidus. It is well known that, during thirst, the blood of these patients undergoes remarkable concentration and urinary flow decreases at the same time. According to data obtained by Podhradszky (1940a) the colloid pressure of the serum of these patients is much increased during the periods of thirst. The increase of pressure is due not only to the increase of protein concentration in the general circulation but also to the coincident increase in the water-binding activity of the proteins. The increase of pressure resulting from these two factors reaches values of 80–120 mm. H_2O (7–8 mm. Hg) and so attains to a third or a quarter of the total physiological colloid pressure of the serum (300–400 mm. H_2O). In his experiments on dogs Podhradszky (1939) showed changes in tubular function under less pronounced (40–60 mm. H_2O) pressure variations. Consequently it seemed likely that the far greater physicochemical energy change in the sera of patients with diabetes insipidus would also affect kidney function.

Two cases of diabetes insipidus—one in a man and one in a woman—were experimentally investigated. The man's disease followed fracture of the base of the skull, whereas that of the woman seemed to be idiopathic. Both patients consumed more than 10 litres of water a day. We carried out three complete experiments—two of them, separated by an interval of two years, on the man. In spite of the small number of experiments, the agreement of the results in the two cases and the shortage of chemicals required for creatinine clearance justify publication of the work we have done so far.

METHODS

Creatinine and chloride clearances were measured in one-hour periods three times in twenty-four hours: the first in the morning, when the patient was allowed to drink freely; the second after ten hours' complete abstention from fluids; and the third next morning, after intake of fluid had again been allowed without restriction. Thus, during the first and third phases of the experiment the patient's water metabolism was in a balanced state, whereas in the second phase the patient was forced to reduce expenditure of fluids to the greatest possible extent.

Creatinine was measured colorimetrically, and chloride by Korányi's method. Urine flow was measured hourly during the twenty-four hours of the experiment. In the samples of blood drawn for the clearance tests, the absolute colloid pressure of the serum was measured by the method of Krogh and Nakazawa, and the total and partial concentration of the proteins by Howe's method. From these data the albumin/globulin (A/G) ratio and the reduced colloid pressure (the pressure exerted by 1% of the serum-proteins) was calculated.

nd tubular resorption reduced, with a consequent crease in urinary flow.

The changes seem to be proportional to the alterations f pressure.

Glomerular and tubular function may thus be con-derably increased or inhibited by the physicochemical hanges of energy dependent on the protein picture.

The mechanism regulating the protein picture may be e of the factors that determine kidney function.

POSTSCRIPT

Since this article was written Prof. E. B. Verney's 946) work has been published. In the light of his ork the question arises whether osmoreceptors are sceptible to colloid concentration—or rather to colloid motic activity—of the blood; and, if so, how far is line diuresis attributable to that. The possibility that ch a regulating mechanism, with its centre in the pophyseo-mesencephalic system, may participate in was mentioned by Podhradszky (1939). But in that e too, the possibility remains that physicochemical ergies set free by changes in the blood-proteins are ally—i.e., in the kidney—involved in the mechanism urine formation. If, on the other hand, osmoreceptors e not susceptible to colloid activity, the rôle of the roteins is probably that described in our present paper. he fact that quality as well as quantity of the proteins ems to be subject to active regulation calls for attention. may well be that, though osmoreceptors react to their tivity, physicochemical work is performed by them the tissues of the kidney too.

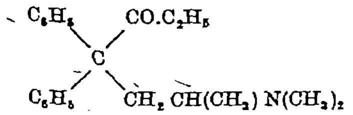
'Amidone,' also known as miadone and 'Physeptone' this country and 'Dolophine' in U.S.A., is a synthetic nalgesic developed during the war in Germany, where was provisionally called 'Höchst 10820.' It is *dl*-2-ethylamino-4 : 4-diphenyl heptane-5-one hydrochloride:



$$(C_6H_5)_2C(CO.C_2H_5)(CH_2\,CH(CH_3)\,N(CH_3)_2)$$

by them during the inhalation of oxygen containing 3% and 5% carbon dioxide. This is a more sensitive test of their action on the respiratory centre than are direct observations of their depressant effect on normal respiration. All three drugs diminished the response of the respiratory centre to the action of carbon dioxide: morphine produced the deepest and longest depression; pethidine caused an initial depression, but recovery was fairly rapid; amidone produced less initial depression than pethidine, but the effect lasted much longer, with the result that over a period of three hours amidone produced a greater depression of respiration than pethidine. During the investigation it had not been realised that the depressant effects of amidone lasted so long.

Since the analgesic effect of amidone was at least as good as that of morphine, and since it was less depressant to the respiratory centre, it was decided to carry out trials with amidone as an obstetric analgesic. We were encouraged to use it because of its greater analgesic action and because of preliminary reports of its successful use in America. Full details of its use in obstetrics have not yet been published in America.

CLINICAL TRIAL

Pethidine was used for the control cases, because its use in labour is now well established (Barnes 1947) and it is used as a routine in the obstetric department of University College Hospital. During the present investigation all the primigravidæ in the labour wards received either pethidine or amidone, hourly observations being recorded on special charts. All results were watched or checked by the same observer.

Dosage

The cases are grouped into two series according to dosage. In the first series pethidine was given in an initial dose of 100 mg., usually followed in an hour by another 100 mg. The first dose did not always give relief. Amidone was tried in various doses. It was at first given in the same way as pethidine, 10 mg. followed by another 10 mg. in an hour's time, 10 mg. of amidone being about equivalent in analgesic potency to 100 mg. of pethidine.

In an endeavour to get better results higher doses were tried: four patients began with 15 mg., ten with 20 mg., and three had 5 mg. or 10 mg. a quarter of an hour after 10 mg. had been given without much effect. Finally, in one case we gave three doses of 20 mg. in 16 hours, and this had a pronounced depressant effect on the baby. At the time of the deliveries we did not always recall which drug had been given, but on looking back over the records we found that where there had been some depression of the baby it was mostly amidone that had been given.

influence glomerular and tubular function; and (2) what explanation can be found for the difference between Podhradszky's (1939) results and our present ones—i.e., why changes of colloid pressure of the serum in his experiments mainly influenced tubular function, whereas in our experiments both tubular and glomerular functions were markedly affected by changes much the same from a qualitative point of view, only shifting on a larger scale.

(1) The first question can be answered partly by the well-known fact that, *under physiological conditions*, filtration in the glomeruli (blood-flow and permeability of the blood-vessels being regarded as constants) is directly proportional to the filtration pressure. The filtration pressure, being the difference between the arterial pressure of the vas afferens and the colloid pressure of the serum, can be influenced by altering either or both of its determining factors. With a constant arterial blood-pressure the rise in colloid pressure diminishes the filtration pressure, and glomerular filtration is therefore slowed; whereas a drop in colloid pressure leads to increased filtration pressure and hastens glomerular filtration. This has been proved by experiment and in practice so often that our results speak most decidedly for the glomerular filtration theory.

But it is equally conceivable that the colloid pressure of the serum-proteins also affects tubular resorption. The glomerular filtrate that streams through the tubules towards the calices has no colloid pressure at all. The blood that has passed the glomeruli and undergone a remarkable concentration by the filtration process streams towards the dense capillary network of the tubules. The glomerular filtrate is separated by only a single layer of cubical tubular epithelium from the blood in the tubular capillaries, the colloid pressure of which—owing to its greater protein concentration—is even higher than that of the circulating blood. It seems almost impossible in these circumstances that the tubular epithelium and glomerular filtrate could remain unaffected by water-binding power of the glomerular capillary blood. Histological and physical conditions thus suggest that a rise in colloid pressure may inhibit glomerular filtration and increase tubular resorption; lowering the colloid pressure, on the other hand, may have the opposite effect. So the final result of any rise in colloid pressure would be a reduction in urinary flow, whereas any drop *in the colloid pressure would increase urinary flow.* Our present results support this supposition, the more so since the changes observed in the glomerular and tubular functions seem to be proportional to the physicochemical energy changes originating from the changes in the protein picture.

trates o
ments while trea
invasion unrelated um-
es trav.—JOSEPH T. WEAL
947, p. 1618.

(2). The discrepancy between the results of the two sets of experiments can be explained partly by the different mechanisms involved, and partly by the different quantities of energy acting in the two experiments. In the anæsthetised dogs the functions of some complementary factors—e.g., variations of the arterial (glomerular) blood-pressure and secretion of antidiuretic hormone—may be altered or suspended, with the result that the kidney of an anæsthetised animal works very differently from that of our patients. Moreover, Podhradszky (1939), in his experiments on dogs, maintained the arterial blood-pressure at a constant level; hence changes in the filtration pressure might have occurred only as a result of the changes produced in the colloid pressure. By alternate administration of pure *Ringer solution* and of *Ringer-gum solution* he obtained changes in the colloid pressure of 40–60 mm. H_2O, which correspond to $^1/_5$–$^1/_6$ of the absolute colloid pressure and to $^1/_9$–$^1/_{12}$ of the filtration pressure in the dog. In our experiments the changes in colloid pressure range from 80–120 mm. H_2O, which is $^1/_3$–$^1/_4$ of the absolute colloid pressure and $^1/_5$–$^1/_7$ of the filtration pressure in man. The physicochemical energy set free by the changes of the protein picture in our experiments is absolutely and relatively much greater than that in Podhradszky's (1939) experiments on dogs, and this is perhaps the most important factor that explains the different results of the two sets of experiments. It seems clear that glomerular filtration needs a more pronounced change to become altered to any well registrable extent than does tubular resorption, even relatively small changes in which may greatly modify the urinary flow.

Gömöri and Podhradszky (1937) have shown that, after copious loss of salt and water, the plasma may become so condensed that colloid pressure reaches the level of glomerular blood-pressure. In such cases filtration pressure ceases to exist; and, since there is consequently no filtration at all, kidney function stops completely in spite of an intact kidney. Podhradszky's (1939) later experiments on dogs and our present investigations both show that the colloid pressure dependent on the protein picture may influence kidney function not only in cases of such extreme changes as described by Gömöri and Podhradszky (1937) but also if the change in pressure, compared with the absolute colloid pressure and filtration pressure, is relatively small. The organism may thus modify kidney function by adequate regulation of the protein picture.

SUMMARY

During unrestricted water intake, the serum-proteins of patients with diabetes insipidus are mostly hypo-active, and their reduced colloid pressure is below normal.

During thirsting periods the blood of such patients becomes concentrated, while the activity of the proteins increases, and so absolute colloid pressure rises by 25–30%.

Simultaneously with the rise in colloid pressure, glomerular filtration is reduced and tubular resorption increased, and so the flow of urine lessens; on the other hand, if pressure falls, glomerular filtration is increased

SUMMARY

midone was given to 62 carefully observed primividæ in labour, and pethidine to 85 controls.

midone relieved the pains of labour similarly to hidine, but had a much more depressant effect on the y, particularly when given over four hours before very.

or this reason it seemed unsafe to go on and the estigation was discontinued.

midone is not recommended as an analgesic in labour.

his investigation was undertaken at the suggestion of f. W. C. W. Nixon, director of the obstetric unit, University ege Hospital, where special facilities are given for research relief of pain in labour. We also thank Sister Billing and staff for most helpful coöperation.

POTASSIUM CHLORATE POISONING

REPORT OF A CASE

SUSANNA GORDON
M.B. Lond.

J. A. H. BROWN
M.B. Lond.

From Chase Farm Hospital, Enfield

POTASSIUM chlorate poisoning is rare nowadays but resents several interesting features, in particular the tabolic changes which it produces. Many cases were orted at the end of the 19th century and in 1911 tthaus collected 155 cases, but since then only a few re been recorded. The published work was reviewed Cochrane and Smith in 1940.

Poisoning by potassium chlorate has usually arisen m mistakes in dispensing or unusual sensitivity to derate doses. The lethal dose seems to be extremely riable, as does the period elapsing between administran and onset of symptoms. Gastro-intestinal disturbces are common. Most investigators have mentioned unusual colour of the skin, and some have found thæmoglobin in the blood. The exact cause of death s been doubtful in most cases, though anuria is somenes recorded. The case described below shows some usual features but seems to illustrate the toxic effects potassium chlorate.

CASE-RECORD

A housewife, aged 61, was admitted to hospital on Sept. 12, 45, with a history that for 6–10 weeks she had sucked enty 5-grain tablets of potassium chlorate daily, because e believed that they would cure the cancer she imagined s growing on her tongue. On Sept. 8 she collapsed and was ted to have an abnormal colour. She had no vomiting or arrhœa. She refused hospital admission for 4 days.

On admission she was an obese woman, conscious, and not any apparent distress. She was not dyspnœic or orthoœic. The skin and mucosæ were deep grey-brown, and e scleræ dark yellow-brown. There was no evidence of y organic lesion of the tongue. Pulse-rate 90 per min.; gular pulse of good volume. Blood-pressure 130/80 mm. Hg. e venous pressure, measured from the sternal angle, was t raised clinically. The heart and the respiratory and rvous systems showed no abnormality. Liver and spleen ere not palpable.

Investigations.—Methæmoglobin was present in the serum admission and was detectable until Sept. 15. There was methæmoglobin in the washed lysed corpuscles at any time. e had not the equipment to make quantitative estimations methæmoglobin.

The hæmoglobin was 50% (Haldane) on admission, and e red-cell count 2,340,000 per c.mm. The blood-count se only slightly despite several intravenous infusions of ncentrated red cells.

On Sept. 13 the following values were obtained, but could not be repeated: serum-potassium 29 mg. per 100 c.cm.; plasma pigment 134 mg. per 100 c.cm., bilirubin 0·9 mg. per 100 c.cm., CO_2-combining power 52·8 c.cm. per 100 c.cm. The serum Van den Bergh was negative until death.

On Sept. 12 the urine contained hæmoglobin but no methæmoglobin, and thereafter no abnormal pigment was found. All specimens of urine contained about 70 mg. of protein per 100 c.cm., but no casts were seen. The urine was alkaline from Sept. 13.

Treatment.—Intravenous infusions of 4·28% sodium sulphate were given daily (about 1000 c.cm.) besides fluids by mouth and moderate doses of alkali. The urinary output rose after 31 hours' anuria, but the urea-concentrating power of the kidneys fell steadily, and the blood-urea level rose. Methylene blue 250–300 mg. and ascorbic acid 2500–3000 mg. were given daily in the sodium sulphate infusions (see figure).

Course of Illness.—Throughout her illness the patient was mainly rational, with intermittent confusion. Her colour improved steadily, but at the time of death both skin and mucosæ were still brown. At no time was there any vomiting or diarrhœa. The blood-pressure ranged from 130/80 to 120/70 mm. Hg. She showed no sign of circulatory failure, despite the intravenous administration of a large volume of fluid, until about 30 hours before death. There was then a rise of venous pressure, the liver became palpable, and there were signs of early pulmonary œdema. Intravenous infusions were stopped, and the signs of circulatory overloading receded, but the patient died suddenly and unexpectedly at 9 P.M. on Sept. 18.

NECROPSY

The body was that of an obese woman, with œdema of the dependent parts.

Brain: slight œdema, with senile atrophy of the cortex in the region of the vertex; pituitary body healthy.

Chest: a little clear yellow fluid was present in both pleural cavities; there was moderate œdema of both lungs.

Heart: myocardium soft, showing fatty change; no evidence of valvular disease.

Kidneys: soft and large (right kidney 11 oz., left kidney 12 oz.), showing fœtal lobulation; petechiæ were present on the surface, but the capsule stripped easily; the cortex showed brownish streaking.

Liver: weight 72 oz.; dark brown, with pattern diminished owing to cloudy swelling.

Spleen: weight 8 oz.; multiple petechial hæmorrhages.

HISTOLOGY

The *kidneys* showed no pathological change in the glomeruli beyond an excess of red blood corpuscles in the glomerular tufts. The first convoluted tubules contained a considerable amount of amorphous eosinophilic debris. The second convoluted tubules showed large dilatations and contained many casts of granular acellular dull brownish-red material, in striking contrast to the brilliant pink of the red cells in the adjoining congested capillaries. Many of the tubules were completely blocked by the pigment casts. The epithelium showed areas of cloudy swelling and necrosis, but mitoses and regeneration of the tubular epithelium were also evident.

The *liver* was congested. Kupffer cells were very prominent and filled with a brownish pigment, which was also abundant in the liver cells. The *spleen* showed congestion, hæmorrhages, and the same pigment. No significant histological change was found in any other organ.

DISCUSSION

The toxic action of potassium chlorate probably depends on the individual actions of the anion and kation of the molecule. The poisonous effects of potassium salts are well known, and the more acute cases of potassium chlorate poisoning are probably due mainly to the potassium ion (Stokvis 1886).

So long ago as 1876 Jaderholm recognised that one of the toxic actions of potassium chlorate was to produce methæmoglobinæmia. The conversion of hæmoglobin to methæmoglobin by potassium chlorate takes place readily in vitro but less readily in vivo (Ulrich and Shternov 1928). Riess (1882) and Huber (1912) suggested that the action of potassium chlorate on the red blood [illegible] lysis. Richardson

All patients were given trichlorethylene from the end of the first stage, if they needed it, with a Freedman's inhaler.

RESULTS

The results obtained in the two series are summarised in the accompanying table.

Contraction of Uterus.—Both pethidine and amidone had a variable effect on the length of the contractions and the interval between them. The commonest finding was a temporary lengthening of the interval. For example, in one case an interval of 1–2 min. became 7 min., then 5 min., and by half an hour 1–2 min. again. Often there was no effect, less often a shortening of the interval. With this change of the interval the length of the contraction was usually shortened temporarily, though in some cases it was lengthened or unaltered. The strength of the contractions, estimated roughly with the hand on the abdomen, did not seem to be altered. Not all the contractions were closely watched in this way; often the patients were left to sleep.

Though the number of cases is far too small to assess the length of labour statistically, there is a general impression that by relieving pain and anxiety pethidine tends to hasten labour. Amidone seemed to have a similar effect. One patient, beginning to feel distress, with cervix 3–4 fingers dilated, was given 15 mg. of amidone. She woke up an hour and fifty minutes later to exclaim that she thought "something was coming," which indeed it was—the baby in the bed.

Pain.—Being subjective, analgesia is not easy to assess accurately. Some patients volunteered expressions of relief and pleasure, which were a comfort to the observers. Otherwise they were questioned. Temperament always affects the answers to such inquiries; some patients, for example, report relief in their willingness to please and be helpful. The expression on their faces tells much, the anxious furrows smoothing out when there is relief. All were questioned later; there was a varying amount of forgetfulness then. Complete amnesia, however, was rare. In the majority, even when there was no relief during the contractions, there was rest in between. They said later that they had "no longer cared," were not waiting anxiously for the next pain, could relax and forget about it. Many went to sleep, stirring only for the pain (which might be as bad as before). In all this the two drugs similar, but amidone seemed to give less euphoria.

Other Effects.—Effects on fœtal heart-rate and maternal respiration, pulse, and blood-pressure were noted in several cases. The fœtal heart-rate was little altered but sometimes slowed a few beats per minute. Maternal respiration-rate often dropped—e.g., from 24 to 20 per min.—and the pulse was usually slowed; blood-pressure, especially the systolic, was slightly lowered—e.g., from 150/90 to 130/90 mm. Hg—but sometimes raised. These effects could have been due to relief of pain. In both groups of patients there were various degrees of dizziness, thirst, and nausea. There was less vomiting with amidone.

Second Stage.—If well managed, by the time they had to "bear down" in the second stage the patients were rested and refreshed and worked well. If they had had insufficient sedative they were tired; if too much sedative they were over-sleepy. There was no pronounced difference between pethidine and amidone in the second stage.

Condition of Infants.—The chief difference between pethidine and amidone appeared in the action on the babies. The exact blueness of newborn babies has not been measured colorimetrically, but babies born under the influence of pethidine appear bluer than those born without any sedative. They are usually vigorous, however, and cry well. Sometimes, although they are firm in tone, move their limbs, and screw up their faces, the first good cry is delayed. Only occasionally, where the labour appears to be normal, is there sufficient hypopnœa to make the baby go limp and cause anxiety. With amidone, where the first dose had been given over four hours before delivery, both the proportionate incidence and the degree of depression were greater. It was for this reason that the second series stopped at 14. We found ourselves rather anxiously selecting cases with prospects of being completed quickly; hence the inquiry had ceased to be impartial and scientific. We did not feel justified in continuing. Where the mother had been unrelieved, there was no sedative effect on the baby. Those babies which had been sleepy sometimes continued so for two or three days after birth and were slow to suck.

Third Stage.—This was not longer in the patients who had had amidone; nor was there undue loss of blood.

RESULTS IN TWO SERIES OF MOTHERS

		First series		Second series	
Analgesic		Amidone	Pethidine	Amidone	Pethidine
No. of cases		48	30	14	55
Average total amount of drug (mg.) ..		21·5	215	20	250

SINCE penicillin is readily absorbed from the tissues er parenteral injection and is rapidly excreted by the dneys, to maintain a chemotherapeutic level in the sues it is necessary either to inject an aqueous solution short intervals or by continuous drip, or to administer in some slow-release vehicle.

Both frequent injections and a continuous drip are en impracticable and undesirable. They are difficult carry out unless the patient is in hospital and three- four-hourly injections cause the patient much inconnience, particularly at night. The incorporation of nicillin in a slow-release vehicle undoubtedly offers me important advantages; consequently, there has en much research into methods which delay the orption of penicillin from the site of injection.

The most widely used preparation, developed mainly Romansky and his colleagues, is a mixture of beeswax 5%) and arachis oil containing 100,000–300,000 its of penicillin per ml.; effective blood-penicillin vels persist for eight to twelve hours, and one or two jections a day give excellent clinical results. This rm of preparation may, however, be difficult to minister owing to its viscosity; it is necessary to warm e syringe and suspension to 37–50°C and then inject ith the minimum of delay, using a wide-bore needle. experienced workers commonly find that the needle comes blocked during the injection, and this may cause nsiderable inconvenience. To overcome this diffilty, it has been recommended that individual doses be spensed in separate syringes.

The inherent disadvantages of the present form beeswax preparation and the great demand for the ow-release product make it important that a more tisfactory product should be available, and many odifications have been tried.

Romansky and Rittman (1944) considered that the % beeswax mixture gave the most satisfactory results; ut it is interesting to note that absorption of penicillin om the tissues was also appreciably delayed by the se of lower concentrations of beeswax. Raiziss (1944) ound that simple suspensions of penicillin in arachis oil aintained the blood-penicillin level for a long time. irsh et al. (1947) recommended that pure crystalline enicillin G should be used, since the resulting preparaons have a reduced viscosity at all temperatures.

Slow-release vehicles have been studied for some years the Department of Pharmacy and Pharmacology, anchester University, and the use of suspensions of arious drugs in oily media indicated that, to obtain the aximal prolongation of the effect of a drug, the volume jected should be small, about 0·5–1 ml. being the ptimum bulk, and that there was no significant difference etween the results given by a plain oil vehicle and one ontaining 4–5% of beeswax.

The preliminary work was done on rabbits. Tests ere later carried out with penicillin, and the results ndicate that 1% beeswax in arachis oil forms an excelent vehicle for the crystalline form of penicillin. This reparation was consequently subjected to clinical trial.

PHARMACY

Though the preliminary results indicated that there was little to be gained by the addition of beeswax as regards the maintenance of the effective blood-penicillin level, it was found that there was a disadvantage from the pharmaceutical standpoint in its omission.

When a suspension of penicillin in plain oil was allowed to stand for several days, some difficulty was experienced in rediffusing the penicillin in the oil. A considerable amount of shaking was required to redistribute the penicillin which had settled to the bottom of the mixture. The addition of beeswax removed this difficulty, probably because it carried the penicillin with it in the form of a readily diffusible deposit of about the same density as the oil. Though 2% of beeswax gave a more readily diffusible deposit than did smaller proportions, it was considered that the viscosity of the preparation at ordinary temperature was unduly increased.

The British Pharmacopœia formula uses, for the oily injection of penicillin, the calcium salt of penicillin to the equivalent of 125,000 units per ml. in a vehicle of 4·5% w/v of white beeswax in arachis oil.

The calcium salt is specified for the official preparation because it is almost non-hygroscopic; and, to keep the volume to be injected to about 1 ml., it has been recommended by various authorities that the strength be increased to 300,000 units per ml.

Practically pure non-hygroscopic sodium penicillin is now being prepared, and a supply was kindly provided by Messrs. Imperial Chemical (Pharmaceuticals) Ltd. This proved very suitable for the preparation of the oily injection; it can be ground readily to a very fine powder without the danger of moisture being absorbed, and, when incorporated with the 1% beeswax-oil mixture, it gives a preparation which is satisfactory in all respects. The mixture remains perfectly fluid at ordinary temperatures, and any deposit is readily diffused by gentle shaking and is sufficiently finely divided to pass through a moderately fine needle. No heating is necessary and should be avoided, since on cooling there is a tendency for the beeswax to crystallise.

The formula and method of preparation for 100 ml. of the mixture are as follows:

Penicillin (non-hygroscopic sodium salt)	30,000,000 units
Beeswax (white or yellow)	1 g.
Arachis oil, sufficient to produce ..	100 ml.

The beeswax is added to the oil, and the mixture sterilised by heating in an oven at 150°C for an hour and allowed at the same time to filter through filter paper. When the oil-beeswax basis is nearly cool, the penicillin is triturated in a sterile mortar with a small amount of the basis until smooth, and then the rest of the basis is added gradually and the whole is triturated; the mixture is finally transferred to sterile containers. Aseptic methods are used throughout.

No moisture is present and the preparation is therefore stable at ordinary temperatures for several months.

The crystalline sodium-penicillin used for the preparation absorbed only 6% of its weight of moisture when exposed to moist air of 66% humidity and, after two months' exposure at ordinary temperature to such an atmosphere, exhibited no loss of potency.*

TECHNIQUE OF PENICILLIN ASSAY

The assay of serum-penicillin levels was made by the broth dilution method; the test organism was the Oxford staphylococcus, and the broth, containing glucose and Andrade's indicator, was prepared from the formula of Pulvertaft and Yudkin (1946).

Samples of blood were obtained by venepuncture and centrifuged, and the serum was placed at once in the refrigera-

* Detailed comparisons of the hygroscopic qualities and stabilities of different samples of commercially available penicillin are being published in the *Quarterly Journal of Pharmacy and Pharmacology*.

(1937) suggested that the primary action of the drug was that exerted by the chlorate ion on the tissues. He considered that methæmoglobinæmia only followed hæmolysis, and that this action was of secondary importance. It seems possible that hæmoglobin is oxidised to methæmoglobin within the corpuscles, and that the hæmolysis, with liberation of methæmoglobin into the serum, follows (Ulrich and Shternov 1928). In our observations methæmoglobin was never detected in the washed corpuscles but was abundant in the serum; hence we conclude that hæmolysis took place before the formation of methæmoglobin.

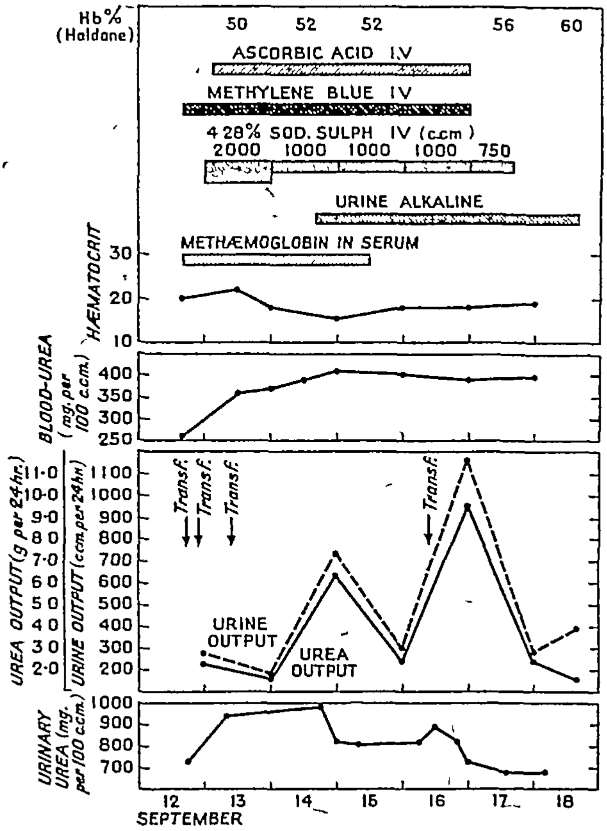

Chart of treatment and findings in a case of potassium chlorate poisoning.

Cushny (1941) states that the acute cases of poisoning are due to simple anoxæmia resulting from transformation of hæmoglobin to methæmoglobin. In the less acute forms hæmolysis occurs and renal damage results from the breakdown products of the corpuscles, which obstruct the renal tubules. In view of the work of Maegraith et al. (1945), a combination of anoxæmia and deposition of pigment causing tubular injury may well explain the profound renal damage in our case. The absence of concentrated urine, coupled with a histological picture similar to that of the crush syndrome (Bywaters and Beall 1941), is to be expected in cases where deposition of pigment has seriously damaged the convoluted tubules. Baker and Dodds (1925) claimed that hæmoglobin is precipitated in the renal tubules at a pH below 6·0, but this finding was not confirmed by Navasquez (1940) or Bing (1943, 1944); renal damage was not produced in their experiments by hæmoglobin injected intravenously, whatever the pH of the urine. On the other hand, the intravenous injection of methæmoglobin in dogs causes severe renal damage if the urine is acid, but not if the pH is above 7·0 (Bing 1943, 1944).

The aim of our treatment was to hasten the reduction of methæmoglobin to hæmoglobin with methylene blue and ascorbic acid, and to combat anoxæmia by slow infusion of concentrated red cells. Potassium citrate was also given to render the urine alkaline and thereby to decrease tubular damage.

The body normally slowly reduces methæmoglobin to hæmoglobin (Stimson and Ray 1927). Methylene blue can act as part of a reversible oxidation-reduction system and is in the reduced, or "leuco," form at the normal reduction potential of the body. It greatly accelerates the reduction of methæmoglobin to hæmoglobin in doses of 1·5–2·0 mg. per kg. of body-weight (Wendel 1937, 1939). Ascorbic acid is also a powerful reducing agent, which will reduce methylene blue to the leuco form rapidly in vitro. Treatment of the anæmia produced by the hæmolysis is important because of the possibility of anoxæmia increasing renal tubular damage. In most types of poisoning which produce methæmoglobinæmia the blood is free from methæmoglobin within 24–72 hours of discontinuing the drug (Harrop and Waterfield 1930, Paton and Eaton 1937). It has not been stated by these workers whether hæmolysis took place or not, but it is to be expected that it would cease about the same time as the methæmoglobinæmia. In our case the hæmatocrit readings did not rise despite transfusion; hence it is probable that hæmolysis continued and further pigment was thereby provided for deposition in the renal tubules. In this case methæmoglobin was present in the serum until eight days after discontinuing the drug. Judging by analogy with the cases mentioned above, it appears that the therapeutic measures aimed at speeding reduction of methæmoglobin to hæmoglobin were ineffective.

The renal aspect of the case was unfortunately true to type. In the hope of producing a diuresis, continuous infusions of sodium sulphate were given. On the last day of life, after several days of anuria and oliguria, the urine output rose. The urea-concentrating power of the kidneys had steadily declined, and the blood-urea level remained high, rising slightly, until the uræmic termination. The slight pulmonary œdema discovered at autopsy suggests that further transfusion would not have been possible, and that overloading the circulation is a very real danger in this type of case.

SUMMARY

A fatal case of potassium chlorate poisoning is described.

Severe hæmolysis, methæmoglobinæmia, and renal damage were produced by the drug.

Treatment with methylene blue and ascorbic acid appeared to be ineffective in speeding reduction of methæmoglobin to hæmoglobin.

Renal tubular damage due to deposition of pigment led to death in uræmia.

Our thanks are due to Dr. Philip Hamill for permission to publish this case; to Dr. Hans Loewenthal, for help with the pathological investigations; and to Dr. E. G. L. Bywaters for advice and encouragement.

hat any improvement noted could not be placed to he credit of thorium-X alone. Alopecia areata with oncomitant curable physical disease or quickly soluble sychological trouble was not treated with thorium-X. or example, cases of alopecia areata in patients suffering rom debility after acute illnesses, girls also suffering from reviously undetected iron-deficiency anæmia, and dolescents overworking for vital academic examinations ere not selected. On the other hand, cases with long-tanding physical infirmities, such as one of muscular trophy following infantile paralysis, and cases with a ifelong personal and often familial psychopathic history ere included.

During these three years 50 cases were chosen and eated. Many of them were referred to other depart-ents at some time or other while having thorium-X eatment. As a result of findings in these departments became necessary to exclude 26 of the cases from this eport for the reasons given above—e.g., a case of ddison's anæmia, married women who became primiparæ, a case with symptoms for which surgical treatment was later given, several cases with uncorrected or mproperly corrected refractive errors, and several cases which dental treatment was needed. Any dental or phthalmological case in which the appropriate treatment was unduly delayed for any reason was excluded. astly, all patients who began treatment or responded or the first time to treatment during the summer f 1945 were excluded, lest any change noted be tributable to post-war causes.

The thorium-X was applied in varnish, in a dosage f 1500 electrostatic units per c.cm., once a month for eriods of from a few weeks to a year.

The details of the 24 cases finally selected are given n the accompanying table.

DISCUSSION

Of the 24 cases in the table, 22 showed satisfactory egrowth, usually within two or three months and not epending on the length of time the alopecia had been resent. Semon (1940) states that recovery of a patch oes not take place under three or four months. In 0 of the cases, including 3 of total alopecia areata and of the band type, the alopecia had lasted over four ears. In 9 of these 10, local treatment with light, asting months or even two years, had been without ffect. Yet in 5 of these 9 cases regrowth started within wo months, in 2 more within four months, and in the emaining 2 within eight months. In the 10th long-tanding case regrowth also took place, but this case had ot had local light. In the case where the beard besides he scalp was partially affected regrowth took place on the calp only. Regrowth was maintained in the case which eveloped thorium-X dermatitis. This case, the first of ts kind to be reported, is described more fully below.

In Corsi's (1943) series, where the selection of cases or treatment was not on the exclusive basis of this series nd treatments were given weekly, no regrowth occurred n the 2 cases of virtually total alopecia: in the 3 cases f total alopecia in the present series regrowth started within six months and was continued for a few months, fter which there was no further increase. The tendency or the new hair to grow pigmented at once, also noted y Corsi, was observed in the cases of total alopecia only. Regarding his suggestion, later approved by Prosser Thomas (1945), that thorium-X should not be applied hile the defluvium is still active. Isaak (1942) reports 2 cases which suggest that hair filters alpha-rays.

In comparing the efficacy of local light and thorium-X two facts emerge: (1) regrowth took place in 9 cases where local light had failed: and (2) the patients now had to attend for treatment once a month instead of from four up to as many as twelve times. Local treatment with light is usually given once a week (Semon 1940), but this often means in a busy department that the patient has to attend two or three times a week to have different areas treated.

Radiodermatitis resulting from subcutaneous injections of thorium-X has been reported (Weissenbach 1938). Regarding a recent favourable report on its use by injection in spondylitis and chronic rheumatism (Hernaman-Johnson 1946) and unpublished reports from other sources on its use in urology, there have been in the past several adverse reports on its use by subcutaneous or intravenous injection (Hamperl 1936, Roemheld 1937, Loup 1937, Zadek 1937, Weissenbach 1938, Bazy and Coste 1938, Deucher and Leigh-Smith 1943), the toxic effects being due possibly to errors in its preparation

* This case was one of long-standing diabetes, and delay in excretion might have been due to renal abnormality.

tor ; series of levels from one patient were invariably assayed together on the same day.

A series of twelve sterile tubes (3 in. by 3/8 in.) were prepared ; 0·5 ml. of the glucose broth was placed in all tubes except the first, 0·5 ml. of the serum was added to the first and second tubes, the contents of the second tube were well mixed and twofold dilutions were made in the remaining tubes except no. 12, which was the control and contained broth only. Inoculation with the test organism was carried out by the addition to each tube of a standard amount of a saline suspension of an 18-hour agar-slope culture containing about 500,000,000 organisms per ml. A comparable series of tubes containing known strengths of penicillin was always prepared as a control ; these results were remarkably constant throughout the investigation. The end-point was taken as the lowest dilution at which the staphylococcus grew after 18 hours' incubation, as indicated by the colour change and the presence of turbidity in the tube.

Inhibition of the organism in the tube containing serum alone was confirmed by inoculation of an agar plate ; cultures were invariably prepared from any tubes giving doubtful readings.

RESULTS

Trials of the preparation were made by two methods : (1) assays of the blood level at intervals after intramuscular injection ; and (2) clinical trials in cases of acute gonorrhœa. The injections were usually made into the gluteal muscles with a no. 2 serum needle, and in no instance was any reaction, local or general, reported. Since the preparation is fluid at room temperature its administration presented no difficulty.

(1) *Blood Levels*

Samples of blood were collected at various times after the intramuscular injection of penicillin 300,000 units in 1% beeswax-arachis oil contained in 1 ml. Assays of the serum were carried out, and the collective results are given in the accompanying table. A control group received an aqueous solution containing penicillin 300,000 units in 1 ml. ; assays of the serum levels are included in the table.

The serum-penicillin levels were maintained much longer after the injection of the 1% beeswax-arachis oil preparation than after that of the aqueous solution. The persistence of the serum-penicillin levels is comparable with that following the injection of the standard 4–5% beeswax preparation. Kirby et al. (1946) found that after the single intramuscular injection of 300,000 units of penicillin in 5% beeswax-peanut oil (1 ml.) penicillin could not be detected in two-thirds of the patients after 12 hours ; when the material was injected subcutaneously, assayable levels were generally present for 20 hours. These levels are considered to be therapeutically effective for all but overwhelming infections with sensitive organisms.

(2) *Clinical Trials*

Slow-release preparations have given good clinical results, particularly in acute gonorrhœa, for which they are now widely used. Clinical trials were consequently made with the new preparation ; 28 proved cases of acute gonorrhœa, 20 males and 8 females, were given an intramuscular injection of 1 ml. containing 300,000 units of penicillin in 1% beeswax-arachis oil. The results were wholly satisfactory.

In all cases a clinical cure was obtained and the usual tests of cure were successfully passed ; there was no complaint of local reaction, pain, &c. There was no difficulty in administering the preparation, which, being fluid at room temperature, was readily drawn into the syringe and injected into the patients with a no. 2 serum needle.

SUMMARY

Effective blood-penicillin levels were maintained and satisfactory clinical results obtained in acute gonorrhœa by the intramuscular injection of 1 ml. of a preparation containing 300,000 units of crystalline penicillin in 1% beeswax-arachis oil. This preparation is fluid at room temperature and can be injected without difficulty.

We wish to thank Messrs. Imperial Chemical (Pharmaceuticals) Ltd. for preparing and supplying the penicillin suspension, and Dr. L. Maddocks and Dr. G. Auckland for their coöperation with the clinical trials.

ALOPECIA AREATA TREATED WITH THORIUM-X

P. J. Feeny
M.B. N.U.I
FIRST ASSISTANT, SKIN DEPARTMENT, THE LONDON HOSPITAL;
DERMATOLOGIST, EMERGENCY MEDICAL SERVICE

Thorium-X is the latest local remedy for alopecia areata, and the only published report is one on the results achieved in 35 cases by Corsi (1943), who continued an investigation initiated in 1937 at St. Bartholomew's Hospital by Dr. F. Jacobson with practical help from Dr. A. C. Roxburgh. The pioneer user of thorium-X in dermatology was Nagelschmidt (1916).

In assessing the value of a substance used locally (such as thorium-X) in the treatment of alopecia areata one must present findings whose value is not obscured by controversial factors. This is because the ætiology of the disease is unknown. There are three theories current (the toxic, the microbic, and the trophoneurotic) each capable of explaining certain cases but none applicable to all (MacLeod and Muende 1946). The suggestion of an endocrinopathic origin is unwarranted in the opinion of Waisman and Kepler (1941), who investigated this aspect in 138 cases. Prosser Thomas (1945) recognised the difficulty of assessing the value of any remedy in this condition, which tends to spontaneous recovery in many cases. Before expressing an opinion based on case-records all cases must be excluded in which a possible toxic, microbic, or trophoneurotic cause had been present and treated. Corsi, in his report, did exclude some treated cases on the grounds of patients ceasing to attend, interfering with controls, or proving unsuitable for unspecified reasons.

PRESENT INVESTIGATION

For the past three years cases for the series now reported were selected from the skin department of Oldchurch Hospital, Romford. In choosing cases for thorium-X many patients were excluded at once, as it was obvious same or a closely similar sign under the name of "pre-fixation tremor," noted in the early stages of three cases of poliomyelitis; so perhaps in the present epidemic it may prove to be less rare than heretofore.

According to the usual conception and authoritative definitions of the term (Myers 1925. Riley 1930). the sign we have described cannot be considered a true nystagmus, though there is a superficial resemblance; on the other hand, it has a certain family likeness to myoclonus. It is therefore interesting to find that Orzechowski (1927) described under the name "opsoclonia" or "myoclonic ataxia" a condition almost exactly resembling it. He speaks of "very rapid and unequal movements. which usually take place in the horizontal plane." He states that the movements are seen chiefly when the eyeballs change their position. and he notes the decrescendo effect of each group. Cerebellar signs of slight degree were always present (hypotonia, tremors, ataxia, &c.), and he also notes the tremor of the eyelids and particularly emphasises emotional lability. All examples that had come to his notice occurred in cases of non-epidemic encephalitis.

Orzechowski's opinion is that this phenomenon is caused by a lesion of the basal ganglia. with or without a disturbance of the cerebellum or its connexions: he envisages the possibility that a cerebellar lesion alone might cause it, but considers it unlikely. Physiologically he classes the disorder with myoclonus, and considers that it is related to the various disorders of muscular movement observed during and after encephalitis, and sometimes in other conditions.

We suggest that the name "opsoclonia" is very apt for the phenomenon we have described, and that it is almost certainly used in the sense intended by its author.

SUMMARY

A description is given of a case of probable polioencephalitis exhibiting a bizarre type of nystagmoid movement of the eyes. It is suggested that this is probably identical with that previously described under the name "opsoclonia" by Orzechowski in 1927.

We are indebted to Dr. T. H. G. Shore. under whose care the patient was admitted to hospital. for permission to describe the case; and to Dr. N. S. Alcock, who saw the patient as neurological consultant, for his opinion and advice

REVOLT FROM THE BEDPAN AND THE ENEMA

G. BOHMANSSON
Dr. Med.
PROFESSOR OF SURGERY, HON. CAUSA

H. MALMROS
Dr. Med.
PHYSICIAN-IN-CHIEF

CENTRAL HOSPITAL, ÖREBRO, SWEDEN

MAN is so constructed that defæcation is best effected in a sitting posture with drawn-up knees, so that the abdominal muscles can come into play. It is therefore unphysiological to defæcate while lying down.

In 1938 one of us drew attention in a lecture to the unnecessary giving of enemas in our hospitals, and showed that at one hospital about 60,000 were administered in about 160,000 attendance days. Enema treatment to such an extent at our hospitals is liable to give patients the impression that the healthy ought also to have recourse to enemas if they do not have a daily evacuation. Patients with chronic constipation often admit that their constipation started in hospital, where they received enemas, and that they subsequently felt obliged to continue them.

When we tried to limit or discontinue the use of enemas, we met with strong resistance from both nurses and patients. The patients re

of disease and convalescence. As THE LANCET[1] points out, "a not uncommon way to die is from cardiac syncope or pulmonary embolism while on the bedpan." Lying down is no protection against such fatal complications, but, if anything, the opposite. One of our assistants. Dr. M. Felländer. has analysed the surgical department's statistics of thromboses and pulmonary emboli in patients not prophylactically treated with heparin or dicoumarol, and finds a death-rate from of 0·14% in 36,789 cases.

ADVANTAGES AND INDI

This arrangement obviates the nec
to move himself, and possesses the fol

(1) Defæcation takes place in a sitting
privacy.

(2) Offensive odour in the ward is avoided.

(3) Cleansing of bedpan and portable closet-pa
eliminated.

The experience gained during the past eight years has enabled us to widen more and more the indications for the use of the portable w.c. chair. Patients and nurses are extremely satisfied, and bedpans are used only by the patients who have to lie down all the time—e.g., those with fractures of the lower extremities in extension. large hip plasters, paresis of the lower extremities. and moribund patients.

Newly delivered women—and patients who have undergone cholecystectomy, gastric resection, or operation for vaginal prolapse are allowed to use the chair one or two days after the operation. Fever is no contra-indication, provided the w.c. is kept well heated. The non-compensated heart is undoubtedly strained far less when evacuation takes place in a sitting posture than lying down. Enemas and bowel washings are practically eliminated. No increased tendency to hernia, heart-

and dosage (Weil and Galabert 1938). Lesser degrees of cutaneous damage from surface application of thorium-X are described by Airey (1945), who, with several years' experience, had seen slight atrophy and telangiectasia in a glossy skin from its long-continued use, but no serious ill effects.

Case 6 in the present series developed an erythema of the scalp after twelve months' treatment. There was no vesiculation, and the erythema had persisted unaltered six months later. The reddened area corresponds to the area painted and not to the scalp area. Regrowth had started on the crown of the head only, and for this reason treatment had been continued. Because of occasional shortages in the supply of thorium-X, due to uncertainty about the amount required, this case was treated fortnightly, each half of the scalp alternately. There may thus have been overlapping of the areas painted, with consequent treatment of some areas fortnightly. It is intended to follow up this case with serial biopsies and photographs.

Though thorium-X is commonly applied fortnightly or even weekly, it is well to recall that its first disintegration product, an indifferent gas with a half-life of about 1 min., may possibly diffuse further into the skin before transformation into more active states and cause demonstrable degeneration at a depth of 0·2–0·3 mm. (Lomholt 1923). This degeneration continues for a fortnight (Lomholt 1936), and Peck (1930) has shown that fair skin takes twenty-three days and dark skin forty-nine days to recover completely; but even then hyperpigmentation may persist for months. Roxburgh (1944) states that the redness persists two or three weeks and then gradually fades and is replaced by pigmentation.

SUMMARY

A series of 24 cases of alopecia areata, including 3 cases of total alopecia, were treated with monthly applications of thorium-X in varnish, for periods ranging from a few weeks to a year. From this series all cases were excluded in which improvement might have been attributable to concurrent somatic or psychological treatment.

Of the 24 cases 22 responded with satisfactory regrowth, and there were 2 failures.

One case after partial regrowth developed an erythema of the scalp which has now lasted six months. It is suggested that in this case, the first of its kind so far reported, treatment of adjacent areas overlapped and was in fact given fortnightly instead of monthly as in the other cases.

Cases of total alopecia responded with partial regrowth. Hitherto, treatment of such cases with thorium-X had failed, possibly because treatment had been given weekly.

The tendency, previously reported, to regrowth being pigmented at once was confirmed in the cases of total alopecia only. In 1 case with bald patches on the scalp and beard regrowth occurred on the scalp only.

Thorium-X is very efficacious in the therapy of alopecia areata and superior to local treatment with light, besides taking less time.

Treatments, however, should not be repeated on the same area more often than once a month.

My thanks are due to Dr. E. Miles, medical superintendent, Oldchurch Hospital, for permission to publish these cases.

OPSOCLONIA

A RARE OCULAR SIGN IN POLIOENCEPHALITIS

D. E. Marmion
M.A., M.B. Camb., M.R.C.P.
MEDICAL REGISTRAR

J. Sandilands
M.B. Edin.
HOUSE-PHYSICIAN

THE PRINCE OF WALES'S HOSPITAL, PLYMOUTH

The current epidemic of acute anterior poliomyelitis is notable for the high proportion of cases with involvement of the brain stem. We have recently seen several cases in which ocular signs dominated the picture, and one we consider striking enough for publication.

A boy, aged 2 years 11 months, a healthy son of middle-class parents, was on holiday when he suddenly developed difficulty and unsteadiness in walking.

Next day it was noted that he squinted and moved his eyes in a curious jerky manner; he was also feverish, irritable, and off his food. The following morning he vomited shortly after getting up, and later that day was admitted to hospital.

On admission he was rather flushed, talkative, and emotionally labile, laughing one moment and in tears the next.

His eyes were the most arresting feature. He had a variable internal strabismus of the left eye, and both eyes showed rapid jerking nystagmoid movements of variable amplitude, occurring in groups of up to half a dozen, the first of each group of jerks being the largest in amplitude and the rest following in decrescendo.

There was no distinction between rapid and slow phases as in true nystagmus; the movements were usually in the horizontal but sometimes in the vertical or oblique planes, and there was occasionally a rotatory element. The movements were identical in the two eyes (with due allowance for the strabismus).

The movements occurred most often just before the gaze came to rest upon a point of fixation, but they also took place at other times, and were intensified by emotion. So far as it was possible to ascertain, they did not interfere with vision.

There were also a fine flutter of the eyelids associated with the movements of the eyeballs; tic-like twitching of the corners of the mouth; a rapid head-nodding tremor of small amplitude, in any plane, as though the balance of the head on the neck was slightly unstable; a slight degree of intention tremor of the upper limbs; and a very ataxic gait, the child walking with evident difficulty and distress on a wide base, staggering and clutching at any available support.

There were no other abnormalities; reflexes brisk and equal; no muscular weakness, tenderness, or spasm; no meningism; and no fever after the first day in hospital.

Lumbar puncture on two occasions gave a normal fluid without increase in pressure; a blood-count was within normal limits.

Progress.—The strabismus started to improve three days after admission and had vanished after a further three days. The other signs, including the emotional lability, increased for about four days after admission, remained stationary for a day or two, and then declined slowly. By the twelfth day in hospital the child was normal, and he was discharged on the fifteenth day.

A tentative diagnosis of polioencephalitis was made despite the normal cerebrospinal fluid.

DISCUSSION

The striking ocular phenomenon which was the principal feature of this case is apparently very rare and has received little attention in the literature. Strickland (1947), however, has referred to what is probably the

failure, or pulmonary embolism has been observed. No death that can be laid to the account of the method has taken place during these years.

The relief in routine work that the portable w.c. chair brings is considerable. Nurses and probationers are as satisfied as the patients, who have no words to describe their delight at escaping the bedpan. Naturally, a patient who is seriously ill should not be left alone in the w.c., but he or she can be assisted there by the nurse just as well as when in bed. The water-closets must be made somewhat wider to allow the nurse to enter and help the patient. An account of the method was published[2] in 1939; it has quickly become popular and is now used in most of the Swedish hospitals.

Sequeira's "Skins" has for many years been a leading full-size British textbook on the subject. Though twenty years have elapsed since the last edition, the authors have brought the work up to date without destroying its original character or spoiling its readableness. The senior author, having lived for years in the tropics, has developed the sections on tropical skin diseases. The relationship between psychological medicine and diseases of the skin has been properly stressed, and an important section has been added on the legal aspects of industrial dermatitis, with a brief useful account of the Workmen's Compensation Act. Illustrations are plentiful and good.

A Textbook of Medicine

(7th ed.) Editors: RUSSELL L. CECIL, M.D., SC.D., professor of clinical medicine, Cornell University; assisted by WALSH MCDERMOTT, M.D., asst. professor of medicine in the university. London and Philadelphia: W. B. Saunders. 1947. Pp. 1730. 50s.

Cecil's Medicine presents a wide cross-section of American teaching, and it is impossible to pick out specially any one of the 150 contributors who have coöperated in this really representative book. The several new coloured illustrations, and about 250 diagrams and photographs, are of varying quality and value. There are some 16 new articles, and a much larger number of completely revised sections. Most subjects are approached by way of a brief historical survey, and a few principal references are given at the end of each section. The balance of the whole is a little uneven: in some parts the teaching seems a trifle vague and ill defined, while in others it is brilliantly clear, concise, and informative. Readers will find some interesting differences between American and English opinion, and will hesitate to adopt all the advice in detail. The early stages of the medical treatment advised for simple peptic ulcer, for example, requires hourly feeds from 7 A.M. to 7 P.M.—not later—at first, and after two or three weeks 9 feeds between 8 A.M. and 6 P.M., with, in addition, 13 doses of alkaline powder of $^1/_2$–2 drachms, and a final gastric lavage at 9.30 P.M. What a day for the patient, let alone the nurses!

The section on diseases of the nervous system has been taken over by Dr. Wolff, who presents his subject well. Poliomyelitis and encephalitis are included in the section on the infectious diseases, however, and so is *syphilis of the central nervous system*. As a rule full instructions for treatment are given, but in places the reader may remain uncertain about what he may try to do for his patient. Thus in the treatment of cardiospasm no precise mention is made of bougies, octyl nitrite, or surgery. The use of streptomycin and of penicillin are in general well described.

Cecil's Medicine remains a first-class textbook—complete, reliable, well printed, well indexed, full of information, and with a wealth of authority behind it.

Pasteurisation (2nd ed. London: H. K. Lewis. 1947. Pp. 296. 21s.).—Mr. Harry Hill's practical book now records the developments in pasteurisation and other forms of heat treatment which have arisen since his first edition appeared in 1943. He foresees a time when such treatment will be compulsory everywhere, and rightly insists on the need for efficient methods of pasteurisation, especially when the high-temperature short-time process is used.

Surgical Applied Anatomy (11th ed. London: Cassell. 1947. Pp. 560. 20s.).—In his preface to this new edition of Sir Frederick Treves's famous *Anatomy*, Prof. Lambert Rogers, who has revised it, notes that it is probably the oldest textbook of surgical anatomy in current use. The first edition appeared in 1883, and new editions and reprints have followed one another at intervals of one or two years ever since. The honourable list of them on the flyleaf suggests that Professor Rogers is not mistaken in his hope that despite its age the book will still fulfil Treves's conception of a modern account of applied anatomy. The book remains convenient for the pocket, and the 192 illustrations—some in colour—are clear.

Old People's Welfare (2nd ed. Published for the National Old People's Welfare Committee by the National Council of Social Service, 26, Bedford Square, London, W.C.1. Pp. 72. 1s. 6d.).—The new edition of this useful guide to practical work for the welfare of the old has been thoroughly revised and brought up to date. A new introduction describes the growth of the movement, and a chapter has been added on occupational activities. These are mostly such pastimes as raffia- and wool-work, bead-threading, the making of scrap-books, painting, and toy-making. The Sheffield Council of Social Service offers the more rewarding solace of allotments to old-age pensioners. Plans for allowing old people to continue in light work, or to undertake simple home industries, do not seem to have matured as yet, though some of the handicrafts suggested in this guide produce saleable articles.

THE LANCET

LONDON: SATURDAY, OCT. 4, 1947

Water-supplies

CONSUMPTION of water in the British Isles is increasing at a rate above the normal average. This is clear from the report of the Metropolitan Water Board[1] for 1946–47. During this summer the drought aggravated the situation, but the problem is not a temporary one. London's supplies of water had been planned on the basis of a steady forseeable increase, calculated from the rise of consumption in past years, but this basis is now proving unsound. The average consumption per head per day in 1946–47 was 51·83 gallons, against the 45·26 gallons which would have been expected at the pre-war rate of increase. The average daily total consumption for 1947–48 looks like reaching 350 million gallons, a figure not anticipated until 1954, and the Board now expect consumption to reach the maximum for which its resources have been planned in two or three years instead of by 1960.

This is only one part of the water-supply picture as a whole. During the past century, piped water-supplies have been extended until 98% of the population of Great Britain is served—a record of which the industry may reasonably be proud. Nevertheless, the 2% without a piped supply represents nearly a million persons; and many of these live in remote villages and farms, where the provision of main water, though it bristles with extraordinary difficulties, is at least as urgently needed as in cities and towns. A piped water-supply to every farm and every village would improve the standard of living for the agricultural population and increase the production of food—its importance in the production of milk, for example, is obvious. The main obstacle is one of finance. Laying mains to remote farms, which may be miles away from the nearest piped supply, is very expensive. As an illustration, take a farm, needing a water-supply, which is 300 yards from a main along the highway. To extend a branch main for 300 yards would cost about £400. In addition the service connexion must be laid and pipes taken to the buildings and farmhouse. Even before the war this cost was prohibitive. Now the figure is out of all proportion to the income which the water undertaking may expect to receive in return; hundreds of country cottages are supplied for less than 10*s.* a year. Moreover, the trouble and expense do not end once the water-supply is laid on; work has then to be done to get the water out again, and this involves a further outlay on sewerage and sewage-disposal schemes. The Rural Water Supplies Act of 1934 placed at the disposal of the Minister of Health £1,000,000 to assist in the provision or improvement of schemes of water-supply in rural areas. The money was distributed by the Minister in lump-sum payments to local authorities towards capital expenditure on approved schemes, and, in fact, £9,000,000 worth of work was done with the Ministry's aid. This suggests that water undertakings tackled the task energetically within the limits of the Act, but their work did little more than scratch the surface. In 1944 the Rural Water Supplies and Sewerage Act provided a further £15,000,000 for water and sewerage schemes to be executed after the war, and in the same year the Agricultural (Miscellaneous) Provisions Act enabled the Minister of Agriculture to give a grant of up to 50% for laying water to farms and farm buildings. These grants were used to develop independent water-supply schemes and for the tapping of water undertakers' mains. It is largely as a result of these Acts that since 1934 the proportion of the population without a piped supply has been reduced from 5% to 2%. Attempts to reduce this figure still further are now hampered by the familiar difficulties of a post-war period. Restrictions on material and labour prohibit much new work being done, even if plant and machinery were obtainable. Meanwhile demands are rapidly increasing for a variety of reasons which affect rural supplies, even if indirectly. During the war the large numbers of men living together acquired new ideas on hygiene, and the habits learnt in the Services remain active after their return to civil life. These new standards of sanitation coincide with the building of new houses containing baths, sinks, and lavatories for tenants who often come from homes lacking in such fittings. All this means that water undertakings are finding it more and more difficult to satisfy the demands of their old customers and leave a margin for the new building going on in practically every town in the country. So there is little chance of much expansion in piped water-supplies to rural areas for some time to come. The new houses in rural areas should be built close to an existing mains system and not in isolation, and all houses should be built with the internal water system laid out, even if no water-supply exists at the time of building. This would do something towards speeding up future schemes. Local resources must also be developed to the utmost, and research should be pressed forward vigorously towards the development of a cheap material for mains and an economical method for laying them.

Lack of water no doubt causes inconvenience and annoyance to a small proportion of the population. But it is as well to relate this regrettable fact to the background of water-supplies as a whole. No other country in the world enjoys such an efficient supply—even the United States, the fabled land of enterprise, initiative, and high-pressure methods, has over 40,000,000 people without a piped supply, and in France half the population are without one. Nevertheless, the goal should still be to provide every household with an easily accessible supply, adequate in quantity, of appropriate hardness, and conforming to a high standard of bacteriological and chemical purity.

St. Mary's Hospital

VACCINES

For Respiratory Affections

ANTI-CATARRH VACCINE

The ideal time for commencing prophylaxis against the "common cold" is during Autumn. Three graduated doses, or six if preferred, with an interval of from 7 to 10 days between each, are recommended. The vaccine especially designed for the purpose is "Anti-Catarrh Vaccine," containing *M. Catarrhalis,* with *Pneumococcus, B. Pneumoniæ, B. Septus, B. Influenzæ,* and *Streptococcus.*

Supplied in sets of 3 or 6 graduated doses, and in ampoules of 1 c.c.; also in bottles of 10 c.c. and 25 c.c.

INFLUENZA VIRUS VACCINE

A purified and concentrated vaccine for protection against both types A and B influenza virus. It is recommended that a first dose of 1 c.c. be administered early in October, followed by the same dose after two or three months. To afford protection against the secondary as well as against the primary infection, Influenza Virus Vaccine may be combined with Anti-Influenza Vaccine (mixed).

Supplied in 1 c.c. ampoules

These Vaccines are prepared in the Wright-Fleming Institute of Microbiology (late Inoculation Dept.), St. Mary's Hospital, London, W.2. Further particulars on request.

Sole Agents

PARKE, DAVIS & CO., 50 BEAK STREET, LONDON, W.1

Laboratories: Hounslow, Middlesex *Inc. U.S.A., Liability Ltd.*

complications has been the safest. These anti-agents will not replace surgery entirely, because interference with the synthesis of thyroxine often gives rise to hypertrophy of the gland with unsightliness and occasionally tracheal compression and there is the ever-present danger of agranulocytosis, which may arise as long as a year after the start of treatment, while the patient is on a maintenance dosage. Often, too, symptoms recur on maintenance dosage and more and more recurrent cases are coming to surgery. In Dr. LAHEY's experience, the rate of recurrences has been very high in men, and he now advises men not to undergo treatment with the antithyroid agents alone. All cases of thyrotoxicosis at his clinic are now made non-toxic with propyl thiouracil, on the grounds that even in minimal cases of thyrotoxicosis one cannot forecast the degree of postoperative reaction. In this country only patients with a severe or average thyrotoxicosis are as a rule prepared in this way. At Boston the preparatory treatment is given at home, the patient being warned to report any disturbing manifestations. If the patient becomes sensitised and develops a feverish reaction to propyl thiouracil, treatment may be continued with thiouracil. The length of time taken in preparation varies. The basal metabolic rate (B.M.R.) in a primary case drops about 1% a day, whereas patients with a toxic adenoma show a daily fall of about 0·3%, since they store more thyroxine. If the B.M.R is slow in dropping the patient is put to bed in hospital. With a B.M.R. of +50% the preparatory rest in hospital lasts about seven weeks; a B.M.R. of +15% is considered satisfactory. The thiourea drugs give rise to increased hyperplasia, vascularity, and friability of the gland, greatly increasing the technical difficulty of its removal; this difficulty is minimised by giving Lugol's iodine, and at the Lahey Clinic the ideal has been found to be a full course of propyl thiouracil followed two weeks before operation by iodine, the first week in conjunction with the propyl thiouracil and the final week alone. This procedure is adopted because agranulocytosis does not appear after the propyl thiouracil has been discontinued for a week. Patients who rapidly develop myxœdema are taken off treatment and sent home to regain a normal metabolic level. Children no longer present any particular difficulty: 200 under 12 years of age have been operated on at Boston, the youngest being aged $2^{1}/_{2}$. The preparatory dosage of thiouracil is the same as for an adult, and the operation is just as safe. Pregnant women are prepared in the same way with no adverse effects on infant or mother; the ideal is to operate as early as possible in pregnancy. Psychotics with associated hyperthyroidism are made non-toxic with the drug and maintained in a non-toxic state for a longer period than usual to stabilise their emotions Where diabetes and hyperthyroidism coincide, the raised metabolism makes it impossible to control the diabetes, but if the metabolism is first lowered with thiouracil the blood-sugar can be controlled and the patient made safe for operation. In 1921 Dr. LAHEY recommended complete thyroidectomy in cases of hyperthyroidism with advanced cardiac failure; the mortality was 6% but the results strikingly successful; these patients are now also treated with propyl thiouracil and complete rest, and are allowed to become stabilised before operation is undertaken.

When Dr. LAHEY last visited England he watched CECIL JOLL at work, and was astonished at his apparently inadequate exposure and his bloodless teasing method of using dissecting forceps to free the gland and dislocate it forward. But all agree that JOLL's results fully justified this technique. It is Dr. LAHEY's practice to ligate the four main arteries of the thyroid to lessen the chances of postoperative reactions, hæmorrhage, and recurrences, and in every case he demonstrates the recurrent laryngeal nerves and parathyroid bodies; this last proceeding is not the general rule in this country. He implies that it is necessary to ligate and sever all tethering veins—the middle thyroids draining into the internal jugulars, and the inferior thyroids draining into the innominate —so that the lobes can be completely dislocated forward before their section and removal is begun. The infrahyoid muscles are cut transversely in all cases.

In conclusion, Dr. LAHEY remarked how great a change has come over thyroid surgery during the past four years, since the advent of the antithyroid agents. This has been the experience everywhere—in Edinburgh, for example, as speakers at the International Society of Surgery remarked (see p. 517), there has been a striking reduction in thyroidectomies—but all agree that the next four years may show as many changes and still further improvements.

IRON POISONING

IRON tablets are not usually looked on as dangerous. Indeed the average woman seems able to consume six or ten of the common gr. 3 tablets of ferrous sulphate every day for weeks without toxic effects. The pharmacological textbooks take the same view; "general intoxication due to orally administered iron," say Goodman and Gilman, "is almost unknown." The report by Forbes[1] last March of two fatalities in young children who had taken ferrous sulphate tablets was a surprise, in spite of the fact that the doses were large. Forbes's first case was a boy of $3^{1}/_{4}$ years who swallowed 50 tablets of a well-known brand containing gr. 3 of ferrous sulphate together with very small amounts of copper and manganese sulphates; he died 53 hours later and his liver showed evidence of necrosis. The second case was a child aged 1 year who was known to have swallowed 30–35 of the same tablets and died in 30 hours; his liver was not necrotic and aspiration pneumonia following vomiting hastened the end. In May, Thomson[2] reported two more cases of intoxication in children following doses of the same tablets. The first case was fatal; a child of 10 months who had swallowed 39 tablets died in 21 hours and the stomach mucosa was acutely inflamed and necrotic; the liver was not affected. The second child, aged 2 years, obtained only 10 tablets and had vomiting and melæna but recovered. Because of the lack of any firm information Somers[3] estimated the toxicity of various iron preparations in rabbits, guineapigs, and mice. He soon found that the copper and manganese were not important and that it was the iron that caused the animals to die. Very large doses were needed, but with these the animals died quite quickly in coma or convulsions. The autopsies were disappointing in that no lesion that could account for the deaths was found in the stomach, liver, kidneys, or elsewhere. When these results are applied to man on a dose-for-weight basis it is clear that the average adult

Chemotherapy and Cancer

Systematic research has lately been so successful in various scientific fields that there are some grounds for the suggestion that cancer-research workers should give up following clues and embark on a systematic trial of all known organic compounds, in the hope of finding one which will destroy cancer cells and leave normal cells unharmed. Probably more trials of this kind have been begun than have been published or completed. For example, between 1936 and 1944 as many as 977 substances and mixtures of substances were tested at the National Cancer Institute, Washington, on 18,395 tumour-bearing mice. A sustained pursuit of this sort might be lucky, as Edison was in his search for a suitable metal for electric bulb filaments. But unless the job was tackled by hybrid ant-men those employed would soon be clamouring for relief from their ordeal. The strongest argument, however, for following clues is that these clues are still promising enough to lure us on.

What are these clues? The observation that the course of prostatic cancer was modified by orchidectomy led to the idea that a hormone antagonistic to androgen might have a similar action. The idea was confirmed by the administration of œstrogens, which in a few cases appear to have arrested the disease. Urethane, a substance which interferes with and arrests mitotic division in certain cells, was found to reduce the white-cell count in some forms of leukæmia to normal, and, if administration is continued, the count is kept low and the patient benefited at least as much as by X-ray treatment.[1] Urethane sometimes has a favourable effect on prostatic tumours which have failed to respond to other forms of treatment, but its action here is not anti-androgenic. Colchicine, another chemical which arrests mitosis, is too poisonous to the host to be useful in treating tumours. The nitrogen mustards disturb mitosis and have a palliative action in lymphadenoma,[2] a disease related to cancer in that there is a progressive proliferation of reticulo-endothelium. These chemicals have provided starting-points for the synthetic chemists, for their molecules might be so modified as to make them more toxic to tumour cells and less so to the host. The clue of antagonistic hormone action appears to have only a limited application, since, even if antagonists were found for every hormone, many forms of cancer would still go unprovided for. Nevertheless this clue is of great theoretical interest and might lead on to others—for example, the starvation of cells of their peculiar aids to multiplication. Poisoning of the peculiar food of cancer cells has already been achieved in the administration of radioactive iodine for malignant thyroid tumours. Further developments of this idea must await the biochemist's demonstration that other cells require peculiar nourishment and that this nourishment can be made lethal without destroying the host. A lengthy systematic search would have been required to discover this exquisite application of previous observation, knowledge, and theory.

All chemotherapeutic assaults on cancer cells must depend on finding or widening a gap between the lethal effects on them and on normal cells. Failure to demonstrate some such gap detracts from the value of observations, even in tissue-culture, of antibiotic action against malignant cells. Testing antibiotics can be regarded either as part of a systematic search or as a clue-following method. Their potency in high dilution against bacteria makes it imperative to try their effects in malignant disease, but when tissue cells are the object of trial control observations on normal ones is an essential part of any investigation.

Many think that prevention of cancer is likely to be attained sooner than cure. This mainly applies to inaccessible or metastatic growths; yet the statistical studies of E. L. and N. M. Kennaway[3] point to the possibility of preventing skin cancer by raising the standard of living of some sections of the population. The essentials of this rise in standard are probably an increasing use of soap and water. May not atmospheric pollution with specific carcinogenic chemicals derived from coal contribute to the incidence of cancer? The experimental prevention of carcinogenic action by competitive chemicals achieved in recent years by Crabtree[4] and by Lacassagne[5] provides another clue which may one day lead to an advance in prophylaxis. It is one of the attractions of the tumour viruses and of the virus theory of cancer that they provide some hope of prevention in the future. Experimental work on these lines is in its early stages but the tumour agents so far isolated have been found to have antigenic properties, producing neutralising antibodies in the blood, and with some examples of virus tumours animals are immune to reinoculation with the same virus. Out of these observations only preventive measures, not cures, can be hoped for, because once the tumour agent has become established inside the cells it is under the protection of those cells. To sum up: chemotherapeutic attempts are dogged by the problem of the gap in lethal action; serology by the problem of penetration of the malignant cell.

Surgery of Hyperthyroidism

Dr. Frank H. Lahey, director of the Lahey Clinic at Boston, told the large audience which came to the Royal College of Surgeons on Sept 23 to hear his Cecil Joll lecture that in 26,000 operations for hyperthyroidism performed on 23,000 patients the clinic's mortality was 0·75%. This figure is astonishing when one realises that quite 1000 of these patients were so toxic that it was necessary to do a partial thyroidectomy in several stages, before the days of thiouracil. During the past four years, when patients have been prepared with thiouracil, there has been only 1 death—from coronary thrombosis—in 1000 cases.

By bringing down the high metabolic rate to normal the thiourea drugs make the patient safe for operation and remove the need for multiple-stage procedures. Of the three thiouracil agents now in use Dr. Lahey finds that all are equally effective in abolishing symptoms but thiouracil has been abandoned because of its higher incidence of complications, while propyl thiouracil with its 1·25% of have been accustomed, provided these are moderate. In the main, the food habits of the old, he thinks, should not be seriously changed from those which the individual made during middle life, though quantities may be smaller: "the aged may live and maintain good nutrition on a relatively low caloric diet." Vitamin upplements are needed—particularly, he thinks, of B and C. Dr. Pyke and his colleagues found the intake of vitamin B adequate in the groups they studied, but noted that the intake of vitamin D was low. Since this vitamin has an important influence on calcium storage, adequate doses might delay that progressive decalcification of bone which leads to the easy fractures of old age.

WORLD MEDICAL ASSOCIATION

At a conference held in London last year, it was greed to set up a World Medical Association,[1] and a ortnight ago Sir Hugh Lett presided over a meeting of the delegates of national medical associations from 48 ountries to decide on the aims and procedure of the new body. The meeting was stormy. Before the new ssociation was fairly in being, many delegates were nxious to modify some of the articles and by-laws drawn up by the organising committee. But finally it was decided that the W.M.A. should deal with "medical politics," that the unit of membership should be a national medical association and not a country, and that each association should have two votes. Eligibility for membership was defined as follows:

(1) Those medical associations which sent delegates or bservers to the International Medical Conference in London in September, 1946; and

(2) Any other national or territorial medical association which is fully representative of the medical profession in its ountry or territory or of the members of the medical profession of a recognised ethnic group in its country or territory.

It was later agreed that German delegates should not be admitted to the association until organised medicine in Germany condemns the past criminal acts of German doctors.

On Sept. 18, when the first meeting of the new association proper was held, Prof. E. Marquis, director of the school of medicine of Rennes, was elected president, Dr. T. C. Routley (Canada) chairman of the council, and Dr. Charles Hill (London) hon. acting secretary. The atmosphere did not remain peaceful for long, for the routine business of the presentation of credentials revealed irregularities in the qualifications of some delegates; and when Dr. O. Leuch (Switzerland), the treasurer, announced the offer by the American delegates of $50,000 a year for five years, the pace quickened. The money is needed, because the subscriptions of the member associations are inadequate for the work to be done, but many members were unwilling to accept the conditions attached to the gift. Dr. L. H. Bauer, one of the American delegates, explained that the gift came not from the American Medical Association but from industrialists who were friends of the A.M.A. and were anxious to promote the interests of the W.M.A. The money would be under the control of a committee in the U.S.A. comprising 5 doctors and 4 laymen. One of the conditions was that the headquarters of W.M.A. should be in North America, and this was agreed to irrespective of the gift. But a condition which laid down that the council should work out a scheme of associate membership, so that the industrialist donors could attend the association's meetings, was hotly debated. Dr. P. B. Mukerji, president of the Indian Medical Association, opposed acceptance; he preferred to see the W.M.A. self-supporting, even if this meant relying largely on voluntary effort. On a show of hands the gift was refused by 32 votes to 31, but at a recount next day, when some members refrained from voting, it was accepted. Thus the new association will largely be financed—as well as housed—by North America.

STAGGERED HOURS FOR WOMEN AND YOUNG PEOPLE

The shortage of coal and electricity and the unemployment resulting from the closing of factories during the severities of last winter form the background of an order [1] lately issued by the Minister of Labour. This relaxes some of the provisions of the Factories Act, 1937, which restrict the hours and conditions of work for women and for young people under 18. It has been made "to facilitate the spreading of the electricity load by means of staggered hours of work in factories" and it applies to factories using electricity generated outside for any purpose other than lighting or ventilation. In essence, while the total hours of work must not be increased, women and youths over 16 may do their turn of work over any period during the 24 hours; girls of 16–18 may work between 6 A.M. and 11 P.M.; whereas all young people under 16 may start work at 7 A.M. or finish at 6.30 P.M. All three groups may work on Saturday afternoon or on Sunday, provided other rest days are substituted for them. The order came into force on Sept. 22, but no employer may take advantage of it without first obtaining a "certificate of permission" from a district inspector of factories. Presumably such certificates, which will be a valuable safeguard, will not be given except for the express purpose of spreading the electricity load.

The order allows a wide variety of arrangements for staggering hours of work, and the district inspector of factories may allow double day-shift working by women and young persons of 16 or over; he may also sanction day- and night-shift working or a three-shift system for women aged 18 and over and youths of 16 and over. At first sight the relaxations, however expedient they may be, seem to be a retrograde step. In particular, as far as night work for women and young people is concerned, they reverse the carefully considered policy laid down in the Factories Act, 1937, and in the International Labour Conventions of 1920 and 1934. The International Labour Office in written evidence to the Committee on Double Day-Shift Working [2] stated that "everywhere night work was considered undesirable and efforts had been made for many years to eliminate it in all activities where it was not required for technical reasons." A possible danger underlying the order is that, if the electricity suppliers find that by staggering hours of work their task is made easier, they may make strong representations to have the system made permanent. Though the order is presumably designed to meet an emergency, it gives no indication about the time it is to remain in force, but perhaps the fact that it has been made under a defence regulation gives it a transient air. The reasons why women should not work at night are sociological rather than medical, but a good medical case could be made out against working adolescents and youngsters during abnormal and irregular hours. As regards the double day-shift system, the committee which recently considered the matter think that its wider use would make an important contribution to the economic well-being of the country. "But," they add, "the evidence has also convinced us that the system must necessarily involve some measure of segregation and dislocation of family life and other social and would have to swallow some hundreds of gr. 3 ferrous sulphate tablets before there was any danger. But for children the number for a lethal dose is in tens rather than hundreds. Since these tablets are usually dispensed in bottles of 50 or more, an enterprising explorer, mistaking them for sweets, may soon swallow a dangerous dose. These facts have, so far, been hidden in the medical journals, but now the daily press report that the Liverpool coroner has had to consider the death of yet another child, aged 18 months, who swallowed 15–16 tablets. Doctors should therefore warn mothers—and it is usually the mothers who are taking iron—that the tablets *must* be kept out of reach and are dangerous to children. These fatalities are easily preventable and there should be no more.

PENICILLIN OR SULPHONAMIDES FOR CEREBROSPINAL FEVER?

THE striking success of sulphonamides in the treatment of meningococcal infections is due first to the even diffusion and rapid bacteriostatic action of these drugs; secondly, to the virtual absence of sulphonamide resistance in meningococci, at least when the more active compounds are employed; and thirdly, to the ease of their application. Under this treatment, the case-fatality rate has fallen to such low levels, except in infants, elderly persons, and fulminating infections, that it will be difficult to prove the superiority of any other drug, except possibly in these three groups. One of the first reports on penicillin treatment [1] seemed promising, but it was related only to the favourable age-group of Service personnel, and even there an ominous feature was the reappearance of meningococci in the spinal fluid after its disappearance in 4 out of 65 cases. Subsequent reports [2 3] on small numbers of cases were less favourable to penicillin, as was also the larger controlled trial of Vengsarker and his colleagues,[4] who found the clinical and spinal-fluid response to be slower and the fatality-rate higher with penicillin than with sulphadiazine. At the time of the general release of penicillin supplies in this country in 1946 there was a tendency for penicillin to be employed intrathecally as a routine in meningococcal meningitis in addition to sulphonamides, but this practice was the subject of unfavourable comment in our correspondence columns.[5]

The Scientific Advisory Committee of the Department of Health for Scotland has now produced a second report on the treatment of meningococcal meningitis,[6] supplementary to that published in 1944. It compares the results of penicillin and sulphonamide treatments given alternately, as far as possible, to children under 6 years of age. The treatment was carried out in five large hospitals for infectious diseases. The dosage schedule for sulphathiazole (or other active sulphonamide) was similar to that recommended in War Memo. no. 10 of the Medical Research Council. The penicillin scheme of treatment consisted of 200,000 units systemically on the first day of treatment, and 5000 units intrathecally each day for four days for children under 1 year of age, and double these amounts for children aged 1–5 years. The number of cases treated was, unfortunately, too small for statistically significant results to be obtained. Nevertheless, the results exhibit a clear trend in favour of sulphonamide treatment. Although this result was converse to the expectation of the authors it was in line with the impression gained clinically as the trial progressed. The actual figures showed 11 unsuccessful results with penicillin out of 35 treatments, compared with 5 unsuccessful results with sulphonamides out of 31 treatments. When the age-distribution of the two groups is taken into account, however, the superiority of sulphonamides is even more apparent, for less than half of the penicillin cases were in the unfavourable age-group under 1 year, compared with two-thirds of the sulphonamide cases. An additional group of 15 cases, which all recovered, received treatment with both drugs, and, although no conclusion can be drawn from this, the committee has embarked on a further investigation of the effects of combined treatment. Certain minor findings of the report are that sex-distribution may be neglected in comparison of results, that the age-groups under 1 year should be separated from that of 1–5 years, that the occurrence of complications was a most important factor in determining the outcome, and that the duration of illness before admission—that is, delay in starting hospital treatment—appeared to be a factor in worsening prognosis. The complications which are enumerated appear to indicate that all the cases under treatment were the "ordinary form" of the disease. It is to be hoped that in future inquiries the committee will include fulminating septicæmia and other highly fatal forms of the disease, for it is in these that the combination of sulphonamides and penicillin is likely to be most successful.

DIET IN OLD AGE

THE studies of diets eaten by old people in London, published in our columns last week,[1] bear out some findings at the University of Illinois lately reviewed by Prof. Jacob Meyer.[2] He and his colleagues, studying carbohydrate digestion in the aged, found that though their salivary ptyalin is diminished 80% of the carbohydrate they eat is converted into dextrin in the stomach. Its further digestion is probably completed by pancreatic amylase, which is not diminished. Lacking teeth, old people often prefer a soft mushy diet composed mainly of carbohydrate; and he thinks it should not be restricted, even if there is some fear of diabetes: "It is wiser to permit them to have carbohydrates and spill some sugar, than subject them to the distress of weighed and measured diets plus insulin." Gastric secretion, he finds, is reduced in volume and in acid and pepsin content, the only exception being a greater psychic secretion of gastric juice. This increased flow, however, does not aid digestion but merely dilutes the secretion poured out in subsequent phases, so protein digestion is probably reduced in the stomach. Pancreatic trypsin, on the other hand, is as concentrated as in young people; and there is evidence that old people use 80% of their protein intake. Though further studies are needed, Professor Meyer considers that the protein per kg. taken by the old should be about the same as for a normal adult; certainly, he thinks, no drastic change of habit is called for, unless the protein diet has been deficient. "The fear that protein intake may increase renal damage or cause increased tension should not be taken too seriously." Since lipase in the pancreatic secretion is much diminished the tendency of the old to eat less fat than formerly has a sound physiological basis.

Because of their greater intake of carbohydrate, Meyer considers the aged need more vitamin B than the average adult; and he also mentions studies by H. A. Rafsky and B. Newman who showed that large doses of vitamin C were needed before saturation level with this vitamin was reached in a group of old people. The relationship of vitamin deficiency to the ageing process still needs study: he mentions that mental symptoms in the aged have been reported to improve when ample doses of nicotinic acid were given. He sees no point in forbidding alcohol, tobacco, or coffee in amounts to which old people

INTERNATIONAL SOCIETY OF SURGERY

12th Congress of the International Society of y was continued in Edinburgh from Sept. 23 to 26. eeting was attended by 106 members.

REATMENT OF THYROTOXICOSIS

D. M. **Dunlop** (Edinburgh) suggested that the ery and study of the goitrogenic substances and recently of radioactive iodine may be ushering in nd medical era. Patients treated with thiouracil to feel better after a week, but the maximum is not obtained for a month or more. The blood terol tends to rise, but since there is very wide dual variation, its level is not a good index of ss. The basal metabolic rate falls in 10–30 days; ecause its estimation is often inaccurate, this also l not be taken as a guide. Professor Dunlop is l chiefly by the body-weight which begins to se after about a week. The last features to reflect nprovement are the increased pulse-rate and pulse-re. Indeed, some patients, though fully controlled, nue to have a slight persistent tachycardia.

gives 0·6 g. of thiouracil daily for 3 or 4 weeks, hereafter a maintenance dose of 0·2–0·05 g. daily. yrotoxic auricular fibrillation the effect of thiouracil ilar to that of thyroidectomy in that some cases spontaneously to normal rhythm, while some t only after quinidine, and a few persist unchanged te thiouracil and quinidine. Exophthalmos is not benefited by thiouracil; and in this respect idectomy is superior. Eventually the goitre often ses slightly; but with overdosage the gland ges. Hence thiouracil should be used with care or t all with pressure symptoms or retrosternal exten- Pregnancy is no bar to its use; and in Professor op's series the women have been delivered of normal ts free from goitre. Of the toxic manifestations, nulocytosis is the most important, though in his ience it is infrequent. It may occur either during nitial high-dose period or during the subsequent tenance period.

ofessor Dunlop emphasised the need for protracted ment. When the drug is stopped after a few ths the symptoms almost always return: they can, ever, be controlled by restarting treatment. In a cases, cessation of the thiouracil has not been wed by any recurrence; so far as can be told, e patients have been cured.

hiouracil is a most valuable drug in preoperative tment. Its advantage over iodine is that there is critical day of maximum effect; if the surgeon or patient has a cold or other incidental infection, the ration can be postponed without detriment. Sur-ns dislike the high vascularity of the thiouracil gland; difficulty is surmounted by stopping thiouracil 12 days before operation and giving iodine during interval until operation.

f 76 patients treated with thiouracil, 66 have shown lts comparable to those in successful thyroidectomy. 10 there were toxic effects or drug resistance which ed him to recommend thyroidectomy. There has n no death. For young people he considers treatment thiouracil to be much preferable to thyroidectomy. econdary or nodular toxic goitre he has had many cesses, but he still wonders whether thyroidectomy ght not have a better long-range effect on the diovascular disorder.

Mr. K. **Paterson Brown** (Edinburgh) said that the troduction of thiouracil has resulted in a precipitous ll in the number of thyroidectomies carried out in nburgh; but in the last two years there has been a ght rise again. The present practice is to refer all cases to physicians; and patients return for surgical treatment only on the physician's advice.

The use of *thiouracil in preoperative preparation* has gone through three phases. In the first, thiouracil alone was used; this was not satisfactory, for the gland was found to be very friable and very vascular. In the second phase thiouracil was used up to and even after operation, and iodine was given for 10 days before operation; this too was unsatisfactory, for the full effect of iodine in reducing vascularity did not seem to be achieved and there was an undue risk of wound sepsis. Now thiouracil is given until 10–12 days before operation, and iodine alone is then given; he has found that throughout the operation the pulse-rate is lower with this method than with others.

The indications for thyroidectomy in primary toxic goitre are failure to control symptoms with thiouracil, failure to control cardiac manifestations with thiouracil, increasing size of the gland and pressure symptoms, desire on the part of the patient for operative treatment, and toxic reactions with thiouracil. In secondary toxic goitre surgery is still the method of choice, for pressure symptoms are common. There seems to be a danger of subsequent cardiac breakdown even with thiouracil; and there is at least a theoretical possibility of subsequent malignant change.

Mr. Paterson Brown underlined the value of pulse charts during operation. The curve of the chart is more important than the absolute rate. The rate increases with intubation, at the incision, and during the mobilisation of the first lobe—even to 150–170 per min.—but if things are going well no further rise occurs as the second lobe is dealt with; and as the operation comes to an end the rate is already falling.

Complications are uncommon. The most important is postoperative hæmorrhage, which is always due to oozing from the cut surfaces of the gland. Symptoms begin 5–6 hours after operation; and early recognition is vital. There is rapidly increasing dyspnœa, which may be fatal. The wound must be quickly reopened, the clot removed, and a loose gauze pack inserted. The administration of penicillin should be begun. The wound can be resutured after a day or two.

SURGICAL TREATMENT OF BLOOD DISORDERS

Dr. H. N. **Robson** (Edinburgh), discussing idiopathic thrombocytopenic purpura, said that splenectomy should be carried out in chronic cases where bleeding interferes with social or economic efficiency, or where it endangers life. In acute cases it should be undertaken where conservative treatment has failed to control bleeding, and where there is evidence of intracranial hæmorrhage. Splenectomy is contra-indicated in children until medical treatment has been given a thorough trial: it is also contra-indicated where the condition is not idiopathic, and in the presence of spontaneous remission.

Dr. J. R. **Clark** (Edinburgh), dealing with hæmolytic anæmia, said that the indications for operation are the occurrence of symptoms in childhood, the formation of biliary stones, the recurrence of crises, and failure to respond to blood-transfusion.

Dr. R. H. **Girdwood** (Edinburgh) spoke of the surgical treatment of Banti's syndrome. Whipple in 1945 showed that splenic anæmia is a syndrome associated with portal hypertension. The clinical features alone may not indicate the site of the block: and each case should be assessed on the results of clinical and hæmatological examination, barium swallow, liver-function tests, and liver biopsy. Operation should be carried out whenever educational disadvantages for the workers." These disadvantages must be carefully weighed against the technical and economic results of legislation which allows night work for women and young people in addition to the double day-shift.

GUIDE TO CONVALESCENT HOMES

King Edward's Hospital Fund for London has again done a public service, this time by producing a *Directory of Convalescent Homes*.[1] So far, 130 homes have been visited and listed, and it is hoped in time to make the directory complete: visits are being made to homes as their existence comes to the Fund's notice. This is the first attempt ever made to compile a list of convalescent homes, and it represents much painstaking work. The directory is a loose-leaf volume with a serviceable binding; new information will be added as it is gained, so purchasers will receive additional pages from time to time. Each home has a page to itself, on which are set out, under bold headings and in well-spaced type, details of the number of beds, the types of patient accepted, treatment undertaken, including dressings, any special diets offered, the usual length of stay, visiting and receiving days, schooling for children, religion, charges, staffing, hours of rising and going to bed, the name of the nearest station, and the types of recreation available. Some general comments at the end leave space for notes. This information will be exceedingly valuable to almoners, hospitals, and doctors wishing to send patients for a period of convalescence.

The book has been cleverly indexed under three headings:

> *Index I* is an alphabetical list of homes, giving the reference number of each.
>
> *Index II* gives the same information, but the homes are grouped according to the class of patient admitted—men, women, or children.
>
> *Index III* is an alphabetical list of all details contained in the information sheets: it carries references to the various qualifications applying to patients—e.g., type of illness, religion, profession, place of residence, and so on. It is thus possible to look up the special requirements of any patient.

Sir Henry Tidy, in the preface, hopes that the directory will not only ease the work of those who send patients to convalescent homes but expedite the admission and recovery of patients. This useful volume might with advantage be supplemented by a central bureau, on the lines of the Fund's Emergency Bed Service, which would keep track of vacancies in convalescent homes, and thus help greatly in the placing of patients.

The Fund plans, so far as other commitments allow, to help convalescent homes in their post-war difficulties, and to that end has appointed a committee on which there are representatives of users and owners of homes, the Institute of Almoners, and the British Pædiatric and Invalid Children's Aid Associations.

RESPIRATORY DIFFICULTIES IN THE NEWBORN

NEARLY an eighth of the deaths in the neonatal period are ascribed in this country to "asphyxia during or after birth" or to "atelectasis." Any information which will help to reduce this figure is therefore welcome. Gruenwald,[2] of Brooklyn, has studied surface tension as a factor in the resistance of the lungs of newborn babies to aeration, and he suggests a way in which this surface tension might be reduced. He starts from an observation which indicated that whereas in the lungs of stillborn infants all the alveoli are usually uniformly expanded with fluid, in many liveborn infants who have breathed for a few hours or days areas of complete atelectasis alternate with aerated areas for days after birth. The importance of aspiration of amniotic fluid has been stressed in recent years by many writers. Gruenwald takes the view that the normal fœtal lung is atelectatic and that the expansion of the alveoli with fluid is the result of episodes of anoxia. Here is the first practical point—the supreme importance of preventing anoxia at or near term, not only for its disastrous action on the nervous system but also because of its effects on the aeration of the lungs.

In the present discussions on the relief of pain in childbirth this danger of anoxia must not be forgotten. But Gruenwald went on to determine why it was that fluid could so easily expand the lung alveoli while the normal entrance of air seemed often to be relatively inefficient. He devised a simple apparatus to expand at necropsy the non-aerated lungs of newborn or stillborn infants with fluid and with air. The fluid was 0·85% saline with a small amount of indian ink added so that expanded areas could easily be seen by their dark colour. The fluid was introduced through rubber tubing, and a glass cannula was inserted through the main bronchus into one of its branches. In 15 cases tested with up to four recordings for fluid and the same number for air, using very small portions of the lung for each measurement, a much greater pressure was always required to introduce air than fluid. The average relation of pressure of fluid and air was 1 to 2; the smallest difference recorded was 1 to 1·3 and the largest 1 to 4·3. The explanation offered for this difference is that surface tension counteracts the establishment of the very large area of contact between a fluid surface —i.e., the moist alveolar wall—and air, whereas surface tension will not resist the entrance of fluid. The next step was to modify the experiment by using amyl acetate to lower the surface tension; this was either mixed with the air used to test the pressure required to introduce it, or was mixed with saline which was introduced into the lungs, aspirated, and followed by pure air. The pressures required to introduce air showed a definite reduction when amyl acetate was used, amounting to nearly half the difference between the values for pure saline and air. When amyl acetate was used the aeration was also more diffuse than usual.

The practical application of Gruenwald's observations is that substances to reduce surface tension might be usefully introduced into the respirator or other apparatus used to administer air or oxygen to newborn babies.

RADIOLYMPIA

THE radio industry, placing itself on show at Olympia for the first time since 1939, reveals how much it has gained from the impulse of war. Ordinary receiving-sets seem to be little changed from their pre-war counterparts: plastics are now often favoured; and improvements in valves and loudspeakers make for better hearing. One firm offer a special attachment for the deaf. The greatest advance, however, is in the cost, which is between 75% and 100% above that before the war, excluding the $33^{1}/_{3}$% purchase-tax payable on the trade price. There is much in the exhibition to catch the eye and hold the ear: such as a demonstration of aids to the safe landing of aeroplanes; a radio-equipped police car at work; and radar displays. In the electronic section there is a model railway on which three trains, unaided by the hand of man, survive the perils of intersecting lines with inhuman assurance. Only one stand is devoted to hearing-aids—with miniature valve amplification and operating on batteries or the mains. This firm also make attachments for telephone listening, and group-hearing systems for public buildings.

The wireless manufacturer can supply customers in this country with no great delay; and owners of the many sets now uttering only the cracked tones of senility will no doubt flock to Olympia to jump the price and take their choice.

TREATMENT OF CARCINOMA OF THE RECTOSIGMOID REGION

Mr. T. M. **Millar** (Edinburgh) examined the anatomical and pathological justification for the radical abdominoperineal excision of Miles. The chief direction of lymphatic spread from the lower sigmoid colon and upper rectum is along the line of the superior hæmorrhoidal vessels, and retrograde spread down the rectum occurs only after the nodes above the tumour have become blocked by malignant tissue. It is therefore best to undertake anterior resection, by which a considerable part of the pelvic colon above the tumour with the associated lymphatic drainage area are removed; but only a small portion is removed distal to the tumour, o that after an end-to-end anastomosis the patient is eft with part of the rectum and an intact anal sphincter. Wherever it is possible Mr. Millar carries out this operation without preliminary colostomy; but a decision on this point as also on the choice between anterior resection and abdominoperineal excision must be made after direct examination of the tumour and its metastatic pread.

PROTEIN METABOLISM AFTER GASTRIC OPERATION

Mr. A. W. **Wilkinson** (Edinburgh) presented observations made in association with Miss B. H. **Billing**. The nitrogen balance has been studied in 17 patients treated for peptic ulcer by gastrectomy, in 6 who underwent various operations on bones, and in 4 normal controls. The severity of the katabolic phase of negative nitrogen balance after operation cannot be correlated with the extent of operative trauma or the amount of weight lost. It cannot be due to starvation only, for it is not prevented by the administration of protein hydrolysates and glucose during the immediate postoperative period. However, the duration of negative nitrogen balance can be shortened by increasing the rate at which the daily intake of both nitrogen and calories are restored o normal. Differences in the degree and duration of the katabolic phase on the one hand after gastrectomy and on the other after operations on bones suggest that trauma to different tissues evokes a different response in so far as protein and amino-acid requirements are concerned.

SURGERY IN PORTAL HYPERTENSION

Professor **Learmonth** gave the normal intravenous pressures as: in the systemic veins ±140 mm. water; in the portal vein ±65 mm.; and in the hepatic vein 0±10 mm. In portal hypertension, however, the portal venous pressure is increased up to 500 mm. water; the highest portal pressure observed by him was 350 mm. Portal hypertension may be due to intrahepatic obstruction (chiefly cirrhosis of the liver), which is associated with medial hypertrophy of the portal vein and its tributaries, quite comparable to the medial arterial hypertrophy of arterial hypertension, or with intimal thickening and even calcification. Extrahepatic obstruction is due to thrombosis of the portal vein or one of its tributaries, or to cavernomatous transformation of the portal vein. Occasionally, an anastomotic channel develops between the splenic vein and the left renal vein; this he has observed in 1 patient, and it has been described in 5 others.

The choice of operation is based on the site of the obstruction; this is estimated by preliminary investigations into the existence of blood dyscrasia, œsophageal varices, and impairment of hepatic function and by the direct manometric measurement of the pressure in the portal, splenic, and superior mesenteric veins after laparotomy. Portal and splenic venograms are also used. If the block is in the splenic vein splenectomy is curative. If the site of blockage is in the portal vein lienorenal anastomosis is carried out by splenectomy, left nephrectomy, and end-to-end anastomosis of the splenic and renal veins. He has had no opportunity of carrying out a portocaval anastomosis. For intestinal infarction Professor Learmonth considers that anticoagulant therapy is preferable to enterectomy, while for ascites a Talma-Morrison operation or a portocaval anastomosis is indicated.

ADVANCES IN VASCULAR SURGERY

Speaking to the International Society in London on Sept. 16, Prof. **René Leriche** (Paris) declared that most of the notable advances in the technique of surgery of the blood-vessels are derived from Alexis Carrel's work forty years ago on suture, anastomosis, and grafting. The study of vasoconstrictive reactions has led to such procedures as intra-arterial injection of 'Novocain' or of 'Eupaverin,' arterial resection, circumarterial sympathectomy, ganglionectomy, adrenalectomy, and blocking of the sympathetic nerves to eliminate vasospasm. The study of thrombosis, also derived from Carrel, has led to the use of heparin to prevent intravascular clotting. Finally, arteriography has revealed to the surgeon the lesion with which he has to deal.

The introduction of these procedures has greatly facilitated surgery of the blood-vessels. Thus, in resection of a main artery damaged by trauma, sympathectomy or sympathetic block prevents vasoconstriction of the collateral vessels and allows the blood to return to the distal part of the resected artery, so that arterial continuity can be restored by lateral or circular suture or grafting, in which case penicillin and heparin are indicated. Sympathectomy, or sympathetic block, is also useful in dealing with aneurysms and arteriovenous fistulæ. With aneurysms, the collateral circulation can be promoted by compression of the aorta or of the femoral artery. In arteriovenous fistulæ, sympathectomy or sympathetic block is usually sufficient to prevent gangrene, but embolectomy should always be attempted with the use of heparin, which may even allow recanalisation. In late cases arteriectomy should be performed.

In obliterative thrombo-arteritis cures have been effected, lasting up to 19 years, by bilateral ganglionectomy and unilateral adrenalectomy. If large vessels are implicated, resection and ganglionectomy may produce good and lasting results. Ganglionectomy and arterial resection, either separately or together, have also produced good results in senile arteritis, avoiding the need for amputation.

For congenital malformations, such as pulmonary stenosis, patent ductus arteriosus, and coarctation of the aorta, Gross, Blalock, Alexander, and Crafoord have opened a new chapter in arterial surgery, for which Professor Leriche said he could but express his admiration.

In surgery of the veins, heparinisation and lumbar sympathetic block have revolutionised the treatment of phlebitis of the leg. Where there is early massive thrombosis, the thrombus should be removed by operation and the vein either sutured or resected; but this operation is successful only when the thrombus is new—after a few days it is often impossible.

In pulmonary embolism intravenous injection and infiltration of the stellate ganglia with novocain, together with heparinisation, have minimised the need for Trendelenburg's operation.

Œdema, pain, and skin changes due to phlebitis are best treated by ganglionectomy, with or without resection of the segment of vein concerned. Here phlebography is a help.

After trauma the large veins can often be easily sutured, especially the vena cava. A wound of the portal vein must always be sutured, provided a portocaval anastomosis has previously been effected; otherwise it will be fatal.

there is danger of death from hæmorrhage, provided this danger is greater than that of death from liver failure. The choice of operation must depend upon the exact site of obstruction as observed when the abdomen is opened.

Prof. J. R. LEARMONTH (Edinburgh) has carried out splenectomy on 24 cases of thrombocytopenic purpura. Of these, 3 died, 3 retain their symptoms, and 18 are alive and well. The platelet count and capillary fragility rise and the bleeding-time falls immediately after splenectomy; but the return of the platelet count to normal may be slow. He prefers to operate during remission; during a crisis he operates only if conservative measures have failed. In primary hæmolytic anæmia the surgeon is expected to relieve the anæmia and to deal with the biliary complications. The hæmoglobin begins to rise immediately after splenectomy; and the reticulocyte count falls to normal after 5–10 days. The surgeon must satisfy himself that no biliary calculi are left. He carries out choledochography; and if stones are present in the duct he uses solution G for lavage. Acute biliary complications should be treated alone and splenectomy carried out later.

Dr. GIRDWOOD discussed the follow up after operation on patients with these various blood disorders. Of 10 cases of idiopathic thrombocytopenic purpura, 2 had epistaxis after operation; the remainder are clinically well although several still show hæmatological abnormalities.

Of 7 cases of hæmolytic anæmia treated by splenectomy, 6 appear to be well as regards the blood disorder, though 1 is still anæmic. The evidence is in favour of splenectomy for congenital and acquired hæmolytic anæmia, but the final outcome in any individual case is uncertain; the prognosis is less good in the acquired type and differentiation of this from the congenital type is sometimes difficult. In the Edinburgh series none has had a hæmolytic crisis after operation.

The follow up of 9 cases of Banti's syndrome is unsatisfactory in that insufficient time has elapsed to assess the results of treatment in the 7 cases that have survived operation. Of these, 1 died later from hæmatemesis. No other patient had hæmatemesis after operation.

PEPTIC ULCERATION

Prof. C. F. W. ILLINGWORTH (Glasgow) expressed the view that the excellence of the results obtained by subtotal gastrectomy should not obscure the fact that this treatment is not uniformly effective. The mortality is still too high, and careful follow-up studies show poor results in a certain proportion of cases. Moreover, the great frequency of peptic ulceration (it is estimated that there are nearly a million cases in Great Britain) underlines the need for a wider approach to the problem. Essentially, three main purposes underlie this treatment: to control the acidity of the gastric juice, to protect the mucous membrane against its activity, and to put the ulcerated part at rest.

Vagotomy might be expected to reduce the appetite secretion and diminish gastric motility; but Professor Illingworth's experience with the subdiaphragmatic operation has been disappointing. The hypermotility of the stomach characteristic of ulcer cases usually returns within a few years; and then or later symptoms recur. It remains to be seen whether the supradiaphragmatic method will prove more satisfactory; but this technique is open to objection for other reasons. The validity of the theory that the danger period is the interdigestive phase in the night may be doubted. There is scope for investigation of drugs paralysing the parasympathetic endings, and of anti-histamine substances.

Mr. W. QUARRY WOOD (Edinburgh) referred to Somervell's method, which is designed to reduce the blood-supply by ligature of four-fifths or five-sixths of the gastric blood-vessels along with gastro-enterostomy. In a personal series of 42 cases treated in this way he has found the late results to be unsatisfactory. The reduction of acidity is usually only temporary, and in 4 stomal ulceration developed.

Mr. A. G. R. LOWDON (Edinburgh) described the clinical features of gastrojejunocolic fistula. Though rapid wasting is usual the symptoms are sometimes intermittent. The severe diarrhœa so characteristic of the disease is due fundamentally to jejunitis caused by the contents of the colon entering the small intestine and not to gastric contents entering the colon. Therefore the fistulæ are more easily demonstrated by barium enema than by barium meal, and symptoms can be rapidly and completely relieved by proximal colostomy. A two-stage operation is nearly always advisable. At the first stage a defunctioning colostomy is made in the proximal part of the transverse colon; this is simple and effective. Experience has shown that this measure controls the symptoms immediately and allows rehabilitation of the patient for partial gastrectomy as the second stage. Transverse colostomy is to be preferred to the exteriorisation of the ascending colon suggested by Pfeiffer.

d-TUBOCURARINE CHLORIDE AS AN ADJUVANT IN ANÆSTHESIA

Dr. JOHN GILLIES (Edinburgh) described two series of operations, in one of which curare was employed as part of the anæsthetic technique, and in the other conventional inhalational anæsthesia. Curare, used carefully in combination with general anæsthesia just deep enough to damp down the effects of sensory stimuli without interfering with the vasomotor compensating mechanism, provides excellent operating conditions for the surgeon and serious postoperative morbidity, both respiratory and circulatory, is reduced. Compared with full general anæsthesia and spinal analgesia, there is less disturbance of normal physiological functions. The smaller risk of circulatory depression and the apparent absence of shock noted by most observers, must be due to the small amount of general narcotic employed; curare may have some central effect, but its nature has not yet been defined. In the prevention of shock, however, curare *is not a substitute for adequate replacement of fluid* loss during operation. The only method likely to challenge this new technique is that of well-planned and *efficient regional analgesia combined* with very light controlled basal narcosis by means of 'Pentothal' and oxygen or cyclopropane and oxygen.

CIRCULATION IN PERITONITIS

Prof. W. C. WILSON (Aberdeen) described 30 cases of severe peritonitis, 12 of them fatal, which have been studied by serial estimations of plasma and blood volume, and of total circulating protein, albumin, and hæmoglobin. The plasma volume is reduced by as much as 30%; the slight degree of hæmoconcentration observed is insufficient to account for this, and it seems that the change is due mainly to exudation of plasma into the peritoneal cavity associated with intracellular destruction of red cells. In the terminal stages stagnation of blood in various parts of the vascular bed contributes to the reduction in circulating volume. The reduction in total circulating protein roughly parallels that of the plasma volume; but there is a disproportionate and persistent fall in the total circulating albumin which may be due to failure of synthesis by the liver. However, the changes in plasma volume, protein, and albumin are not strikingly greater in fatal than in non-fatal cases; and evidently these changes are not the primary cause of death. The indefinite and little-understood concept of bacterial toxæmia has still to be invoked.

four years, whereas the gastrectomies have been wed up for ten years; the results are therefore d in favour of the vagotomies. The mortality for gastrectomy against 0 for vagotomy) and the ence of recurrent ulcer (3% against 1%) are the most rtant points in which gastrectomy is a worse opera- than vagotomy. Apart from this the functional ts have been almost identical. The unfavourable ts of gastrectomy include gastritis, which may e bleeding; the "dumping" syndrome, which may lisabling but tends to improve with time; some ee of weight loss; and what Dr. Allen calls "G.I. plaints." The commonest undesirable effects of tomy are a feeling of fullness and diarrhœa; in r cases there is persistent ulcer pain and in some r severe bleeding. In the cases which develop late ruction gastrojejunostomy has to be done and this cure them, whereas it has no effect on the sensation ullness. On the basis of these results Dr. Allen ludes that vagotomy will have a permanent and ite place in the treatment of duodenal ulcer.

r. Allen summarised the present position of the tment of duodenal ulcer in seven points: (1) Either rectomy or vagotomy will bring immediate relief lmost all cases. (2) For gastrojejunal ulcer vagotomy he treatment of choice. (3) In younger patients otomy may be tried before gastrectomy is con- red. (4) Vagotomy has no place in the treatment of ric ulcer because of the impossibility of being sure a gastric ulcer is not malignant until it has been oved. (5) The transthoracic approach is essential nsure an adequate neurectomy. (6) Many years of w-up studies are necessary before the operation of otomy can be properly evaluated. (7) For cicatricial truction gastrectomy is the best treatment.

Recurring Dislocation of the Shoulder

rof. W. E. **Gallie**, of Toronto, said that in his erience early superficial operations for this condition, h as the Clairmont procedure, never revealed the ected capsular defect. But passive dislocation during ration shows the humeral head simply slipping ward over the anterior edge of the glenoid into a ovial-lined cavity in front of the scapular neck, a ity formed by detached labrum and capsule exactly described by Bankart.

The first dislocation, occurring as it nearly always s in an active young man of 19–20, is usually indis- guishable from an ordinary traumatic subcoracoid placement; but in 17% the causative exertion is rial. Bilateral dislocation is quite common, and is ual in the 6–7% of cases occurring in epileptics, in om initial displacement most often happens in bed. many patients dislocation is only partial at first, the ad riding up on the glenoid rim and then sliding back, d this is repeated until displacement becomes com- ete; but of course in many instances of true luxation e head only moves forward through a distance equal half its breadth. Patients may complain that moderate duction and external rotation movements give them feeling of instability, because the humeral head teeters the glenoid rim before falling back, and that they ways go in fear of sudden dislocation.

In the typical case, an athletic young man dislocates s shoulder in a ski-ing or football accident; the lesion iffers in no way from an ordinary dislocation, and duction is effected as usual. Several months later ackward leverage of the elbow with the shoulder partly bducted produces a recurrence, and this is followed by ore and more frequent repetitions evoked by less and ss trauma. Inspection of the living pathology shows the rticular cartilage of the glenoid flowing smoothly over he anterior lip on to the scapular neck without obstruction, owing to the separation and detachment of the capsule and labrum, which have not healed down after reduction. It must be assumed that such separation occurs in most cases of ordinary anterior dislocation of the shoulder, and that healing takes place in all save those which become recurrent. It is difficult to adduce any congenital anomaly predisposing to such a failure to heal, though the humeral head is occasionally over-large or the glenoid unduly flat. Even in the double dislocations of epileptics, strong muscular contraction seems to be the prime cause. Prof. J. C. B. Grant's dissections showed that the anterior part of the labrum may be considered part of the inferior glenohumeral ligament; but the firmness of attachment of these structures varies, and it may be that recurrences only take place when ligament and labrum are so firmly fused that they are both torn off the bone together.

So far as operative measures are concerned, Professor Gallie still finds that his original method of 1927, with slight modifications, gives very satisfactory results. It is necessary to block the front of the joint, either by reinforcing the anterior ligaments or otherwise, and it is the remoteness of this region of the scapular neck that is the difficulty. He adopts the usual anterior deltopectoral exposure; the short head of biceps and coracobrachialis are retracted inwards, and subscapularis is held upwards without dividing it. A hole is drilled through the neck of the scapula just inside the rim and half an inch above the inferior border of the neck, and a fascial strip can be drawn through by cutting down on the threaded tip of the drill when it is pushed through into the infraspinous fossa behind. Fascial ligaments are constructed binding the scapular neck to the bicipital groove of the humeral head and to the coracoid process, and subsequent operations and sections have made it abundantly clear that these ligaments function perfectly for the rest of the patient's life. Movements are allowed 4 weeks after operation, and are usually complete in another month. In 175 cases there have been no deaths and only 7 recurrences, 5 being due to placing the new ligaments too low, before it was realised that displacement is always directly anterior; these were cured by placing new fascial bands at a higher level at a second operation. In 2 cases a severe injury caused the recurrence but only one of these went on to frequent repetition calling for another operation.

It was clear that the operation is simple, safe, and reliable, and Professor Gallie concluded by showing a film to illustrate the essential steps in his procedure.

Medicine and the Law

The Brighton Sanatorium Inquiry

After four days' hearing by Dr. N. R. Beattie, a senior medical officer of the Ministry of Health, the public inquiry into conditions at the Brighton sanatorium has ended and the verdict of the Minister must be awaited.

Last November a petition from male tuberculosis patients found its way to a local ratepayers' association, whence copies were circulated to the mayor, the town clerk, and all the members of the borough council. Female patients later signed a petition; some of them were subsequently discharged, and one (Mrs. Guile) died after discharge. The clergyman who conducted her funeral felt so strongly about her case that he used the occasion (thereby incurring the censure of his bishop) to make statements from which one might infer that the borough council and its medical officers were to blame for her death. Apart from such accusations, the allegations mainly concerned the food and the cooking. Dr. S. J. Firth, medical director of the municipal hospital services, and Miss Stringer, chairman of the health committee, were in the witness-box for some hours. The proceedings, recorded in the *Brighton and Hove Gazette* and other

TREATMENT OF FRACTURES

At the third scientific session of the congress, on Sept. 17th, Prof. ROBERT DANIS (Brussels) discussed his experience with some 1300 fractures over the past eighteen years. He was opposed to the views of those surgeons who regard operation as indicated only when closed methods have failed, and he was particularly critical of simple open reduction which relies on complementary external methods of fixation. In his view, operative fixation is destined to become the method of choice for most cases. If, under guaranteed asepsis, the fragments could be fixed and apposed by a pressure regulated at will, then plaster fixation could be dispensed with and rapid consolidation would be inevitable. At the same time articular damage, muscular atrophy, and œdema would be minimised. Such a method of fixation can be obtained by the use of his "coaptors"—metal plates which after being fixed to the bones can be shortened to press the fragments firmly together, thus providing the longitudinal compression which is the essential stimulus to sound ossification of callus. In many cases failure of osteosynthesis is due to an obvious breach of asepsis, the use of a poor-quality metal plate or its imperfect fixation; but there are many other instances without obvious cause for failure which must be due to inadequacy of the pressure exerted in the line of the bone axis across the fragments. The vital importance of axial pressure has been recognised clinically only in the last few years, though its effects have been obvious in tissue-culture and pathological findings for much longer. The coaptors, which can be approximated just as far as the surgeon wishes, supply this compression factor under direct control, and Professor Danis illustrated their use in fractures of the shafts of the forearm bones, of the humerus and femur, and in certain transverse fractures of the tibia. The only other factors necessary to success are a strict no-touch technique, good stainless steel plates kept away from the deep surface of the skin, and a rock-like fixation at the end of operation.

Spiral fractures of the tibia are fixed very simply with a steel wire, and protected thereafter only with a short celluloid splint which does not include the ankle or knee.

Professor Danis favours the use of Orell's *os purum* in operating on cases of non-union, as it is not only well tolerated but very osteogenetic, even in the presence of some infection. He introduces it around the fracture site in the form of little "bricks," and he does not interfere with the pseudarthrosis at all unless deformity or distortion make this necessary. He concluded by illustrating briefly the management of two particularly troublesome fractures. For old fractures of the os calcis with gross flattening of the long arch, he restores the hollowing of the sole by detaching the tuberosity of the bone and fixing it to the body with a nail at a lower level. Old depressed fractures of the tibial plateau can be improved by cutting a wedge from beneath the depressed side and turning this wedge into the long axis of the bone so as to raise the flattened articular surface.

Special Articles

MOYNIHAN LECTURES

DURING the week Sept. 22–27 three Moynihan lectures were delivered at the Royal College of Surgeons, two of which are summarised below.

Surgery of Duodenal Ulcer

In his lecture on Sept. 22, Dr. Arthur W. Allen, president of the American College of Surgeons, explained that he had chosen the treatment of duodenal ulcer as his subject because it is now being critically re-examined by surgeons. About 10% of duodenal ulcers cannot be cured by conservative measures, and until recently subtotal gastrectomy was thought to be the treatment of choice for these resistant cases. But a few years ago misgivings began to arise. Some patients were not made better by gastrectomy and a very few were made worse by the side-effects of the operation.

It is 40 years since Pavlov showed by the experiment with his famous pouch that section of the vagus abolishes the stimulant effect of a meal on the gastric secretion. Why was no progress made along this line in the search for an answer to the problem of duodenal ulcer? Dr. Allen put forward two possible reasons—first, the discovery about the same time of the important rôle played by the hormone mechanism controlled by the pyloric mucous membrane; and secondly, the spectacular results obtained, at least for a time, by the introduction of *gastrojejunostomy*.

Four types of gastrectomy are done by Dr. Allen and his colleagues for duodenal ulcer. In all of them the whole of the lesser curve is removed and as much of the greater curve as will permit the formation of a mechanically sound anastomosis. They differ in their treatment of the duodenum. In the first and most satisfactory method the first part of the duodenum is excised, including the ulcer. When the ulceration is further from the pylorus the duodenum may be divided and safely closed proximal to it. The third type of operation is applied to cases where there is extensive ulceration and adhesions near the pylorus. In these cases the stomach is divided *proximal to the pylorus and then the mucosa of the* pyloric antrum is entirely removed by dissection. Dr. Allen thought that this last step was one of the features of Finsterer's original operation of "gastrectomy for exclusion," but to do the operation without this step is to set up ideal conditions for the development of gastrojejunal ulcer. The fourth type of operation is done for the same kind of case as type three and consists in two stages. In the first stage a type-three gastrectomy is done but without the removal of the antral mucosa. Six weeks later the pyloric antrum and the first part of the duodenum are removed. Dr. Allen himself has not used this fourth type of operation, which has been devised chiefly for the use of less experienced surgeons. Using these operations (chiefly type one) 106 gastrectomies have been done for uncomplicated duodenal ulcer with 4 deaths. Dr. Allen emphasised that the most important cause of death in gastrectomy for duodenal ulcer is leakage of the duodenal stump.

The best vagotomy operation consists in the removal from above the diaphragm of at least two inches of the vagi and the encapsulation of the upper cut ends in a cylinder of silk in order to prevent regeneration. In addition the diaphragm may be opened so as to sever the nerves at their point of decussation. Of 103 such vagotomies done, 75 were for uncomplicated duodenal ulcer with no deaths, 22 for jejunal ulcer with no deaths, and 6 for miscellaneous conditions. In this last group there has been 1 death, which may have been the result of vagus collapse, for the nerves were not injected with 'Novocain' before division, a precaution which should always be observed. Dr. Allen demonstrated the effectiveness of vagotomy by the insulin response before and after operation, and his graphs were convincing evidence of a satisfactory physiological result. Nevertheless at the Massachusetts General Hospital there has recently been a slight falling off in the popularity of *vagotomy in favour of gastrectomy* for uncomplicated *duodenal ulcer*.

Comparison of the clinical results of the two operations shows a very even balance, but Dr. Allen emphasised that the vagotomies have been followed up for not more

In England Now

Running Commentary by Peripatetic Correspondents

THIS week's Pathé Gazette is showing a strange piece exhibitionism: Mirin Dajo is a Dutchman who allows other man to thrust swords through him—and not erely through silent areas, so to speak, but from side side of his upper abdomen in the perilous neighbour-od of stomach and spleen: and again from back to e just below the right lung. The scene of this particular monstration is the Bürgerspital at Basle, and the ctors watching it conduct Dajo, transfixed with his ord, to the X-ray room for photographs. Unfor-nately the resulting films are not shown. The com-nion who operates with the sword takes trouble about carefully pinking Dajo through previous scars and lowing some line well known to him. The most he ts from Dajo is a slight frown: and on withdrawal of e sword there is no bleeding. No-one need doubt the ts: the camera close-up shows the sword going in. e little alp of stretched skin which appears before it rforates the opposite side of the chest, and the cuff skin dragged up by the blade as the operator pushes well through. This stretching of the skin at the point exit seems to be the only uncomfortable part of the siness, for the operator, before he stands back and ows Dajo to display himself, slides the cuff back along e blade until it lies flush with the chest wall.

The trick—if such a genuine performance can be lled a trick—is comparable to that seen in India, where kirs will transfix their necks with knives. In the ck, however, provided the muscle masses are pulled ll forward, a blade can slide across in front of the inal column without encountering any large important uctures. In Dajo's case the sword running trans-rsely through the upper abdomen must pass just hind the stomach, just in front of the spleen, and then front of the spine, escaping the great vessels; and must ally transfix the liver above the level of its hilum. fore piercing the skin again. The blade running rough the right side of the chest must pass below the ssels of the hilum of the lung. Pathé have taken the uble to get an expert opinion on this feat; and a mmentator recounts the explanation. Bullets and her missiles are known sometimes to pass through the dy in much the same harmless way, travelling along embranous planes, and pushing soft viscera out of their y. If a sword could be passed successfully along such safe path, fibrous tissue would form along its course, d it would become increasingly easy to repeat the iracle with each attempt. Moreover, as the scar tissue ew older it would become avascular, and transfixion ould be bloodless. It was evident from the care with hich the operator thrust Dajo through that he was llowing a known course, and he was probably able to dge, from the sensation transmitted to him from the int of the blade, that he was following the line of ar tissue. Moreover, Dajo would probably have let m know if he happened to veer off it. Yes, it was easy see, at this stage, how the thing was managed; but hat about the first time?

* * *

We called it a summer school, but the Germans called "Internationales Medizinertreffen," which shows that mposity dies hard. There were about 150 German udents from various universities and a Swiss and 2 utch students, as well as a Swiss neurosurgeon, a wedish tuberculosis physician, and 3 "Britishers" pharmacologist, a physiologist, and a junior surgeon) lecturers; all but one lectured in German. Lectures cupied all the mornings, and the rest of the day was ken up with informal meetings, excursions, and dances. ubjects covered a wide range with a notable absence of inical general medicine. The whole thing was under e ægis of the Foreign Office, personified by the niversity Education Control Officer. This lady com-ined enthusiasm with energy and drive on such a scale nd with such resulting efficiency that the cynic was mazed; the cynic also developed doubts as to whether ll would be quite well between her and her "higher ps" of the Civil Service and the C.C.G. in the long run.

The Germans took our information "lying down" n very few subjects, notably anæsthesia, penicillin, and such. Usually they produced a badly conducted incoherent discussion designed to prove that our information was out of date, useless to them, and made up of discarded German theories. This was quite untrue, for the lectures were packed with good and fresh meat which they badly needed. Their only technique of blood-transfusion was the direct donor-to-patient method with a three-way syringe. Their only anæsthetics, given by sisters, were chloroform and open ether, even for incision of abscesses in Casualty. Their surgery was very slick from the operative point of view, but the cynic saw nothing new except the intramedullary nailing of fractures (Marknagelung) of Küntscher. This was extremely impressive in its results and advantages, and it would surely be worth while to send a young surgeon out from England to learn from these people (who have already made most of the possible mistakes) the technique, indications, and limitations of a method which might revolutionise the treatment of many fractures. Küntscher's method was received with a flood of abuse and contradiction at the congress of surgeons in Berlin in 1940 but has since gone from strength to strength.

* * *

Ramadan having ended, the Arabs presented us with two chickens as what they called a Christmas present, so we decided to continue the work on hens described by your peripatetic correspondent of July 19.

Your correspondent's observations on the immobilisation of hens with their beaks on a chalk line were corroborated in every detail and also found to work with brown, red, purple, blue, and yellow chalks—all placed in the coronal plane—i.e., at right-angles to the beak and on a neutral greyish background (the top of the officers' mess bar). Lines placed in the sagittal plane had no effect. Various other chalk marks, however, worked successfully in the coronal plane—viz., an interrupted line where the beak is placed in the 2-inch gap; a circle of diameter 3 inches where the beak is placed on the circumference; a cross where the beak is placed either at the intersection or at the end of one arm; and a squiggly spirochætal line where the beak is placed on or within an inch of it. The thinner the lines the better were the results. Both hens would also remain immobile if their beaks were put into a pool of "Sarona Rot," a particularly virulent form of Palestinian "port-type" wine. Finally, all experiments were repeated with the hens' eyes blindfolded—without success (except, for some reason, with the Sarona Rot). It would appear, then, that the effect is due to a visual hypnotism caused by the hen's seeing two precisely similar objects with both eyes at once—an experience which is rare and apparently unnerving for it.

Besides the above phenomena we also noted that if a hen's head is tucked under its wing and the body rocked gently to and fro (as in Riley's Rocking Stretcher) six or seven times, it can be put down in a deep sleep, sometimes even lying on its side with one leg in the air.

Further research with these two subjects will be impossible as they are due to make positively their last appearance to the accompaniment of green peas and roast potatoes. Two pigeons also presented to us we were unable to use experimentally owing to the decision of a black spaniel (who is after all only an honorary member of the mess) to try their effect as a test-meal on his gastric secretion.

* * *

My friend Douglas was always mighty tough and it is hard that one so obviously cut out for big-game hunting should have been condemned by fate to follow the relatively old-maidish and humdrum pursuit of surgery. His latest letter, however, testifies to the old fire that still burns within him. It runs thus:

> Shot a rat this evening outside the kitchen from my *machan* in the consulting-room. I can't describe the agonies of waiting, rigidly motionless in the silent dusk, until at last I discerned the long, low, stealthy form noiselessly advancing on the bait (a nice fresh rabbit skin).
>
> Despite my long wait, and although horribly cramped by my vigil, I was just able to swing down the barrel with the almost imperceptible fluid motion which is the least alarming of all perceptible movements to the creatures of the wild. My eye darted along the sights, my finger tightened on the trigger. "Chock!" said my trusty airgun, and the rat, jumping a full foot in the air, fell back for the last time with a dose of lead (gr. 5) in his innards.

papers, indicate that strong feelings were aroused. It is perhaps not surprising in the circumstances to find sharp differences of opinion and of testimony. One patient, for instance, says she had only a tea-cup of milk each evening; another says he had plenty of milk three times daily. One patient recalls being served with a plate full of maggots; another praises the food and claims that his weight went up 2 stone during six months at the sanatorium. The father of Mrs. Guile suggested to her medical attendant that he was "experimenting" on his patient; her husband wrote a letter of thanks to the town clerk for the treatment of his late wife; "my honest opinion is that she was too ill and irritable to worry about food."

Whatever be the findings of the Minister on the facts elicited at the inquiry, one can hardly doubt that similar allegations have been, and will be, made so long as hospitals are short of doctors, nurses, and equipment, and so long as food shortages give patients and everybody else a ground for grumbling. A memorandum by Dr. Firth was read at the inquiry. When a letter of complaint from 15 patients was referred to the hospital services subcommittee, he had observed that the hospital was a sanatorium in name only; the hospital facilities were not really satisfactory for tuberculosis patients, and extensive alterations and buildings must be planned if true sanatorium treatment is to be given there. His words will be echoed doubtless by hospital authorities elsewhere while medical needs have to take their place in the queue along with other competing claims.

Pending the decision of the Minister on the Brighton case, praise or blame cannot be allotted. Two general comments meanwhile suggest themselves. The public inquiry, held by a public servant, still commands respect and is still regarded as the best method of ventilating grievances of this kind; the umpire's verdict will presumably still be final. Secondly, even if the criticisms are held to have been exaggerated or unjust, it is something that local opinion should be stirred to insist on the highest standard in local health services.

Public Health

Food-poisoning

On Sept. 7, 8, and 9 there occurred at Kincardine O'Neil, an Aberdeenshire village with a population of about 200, an outbreak of food-poisoning which involved no less than 97 people, including the farmer who supplied milk to the village, his family, and his farm-workers. The symptoms consisted of vomiting, nausea, abdominal pain, and diarrhœa, lasting 3–4 days; thereafter most patients recovered rapidly. There was no death.

Investigation at once showed that the only common food was milk; and when the dairy supplying the village was visited it was found that a cow had become ill about Sept. 5 and had been so ill on the 6th that a veterinary surgeon was called. This animal had died on the 7th, and post-mortem examination on the 8th showed signs of severe enteritis with advanced inflammatory changes in the small intestine. The herd at the farm consisted of some sixteen cows in milk; in addition to the animal which had died, another cow had been off her food and two calves had had diarrhœa.

Twenty-one specimens of fæces from various households showed the presence of *Salmonella dublin*; samples of milk obtained from the cows on the 5th and 6th showed the same organism, while a sample of the bulk supply taken on the 9th, after the cow had died, gave negative results. From the material obtained from the carcase of the cow at the post-mortem examination a gram-negative non-lactose-fermenting organism was obtained, and this also was proved to be *S. dublin*. All the other cows and the two calves were then investigated; *S. dublin* was not obtained from the fæces of any cow but it was recovered from the fæces of both calves.

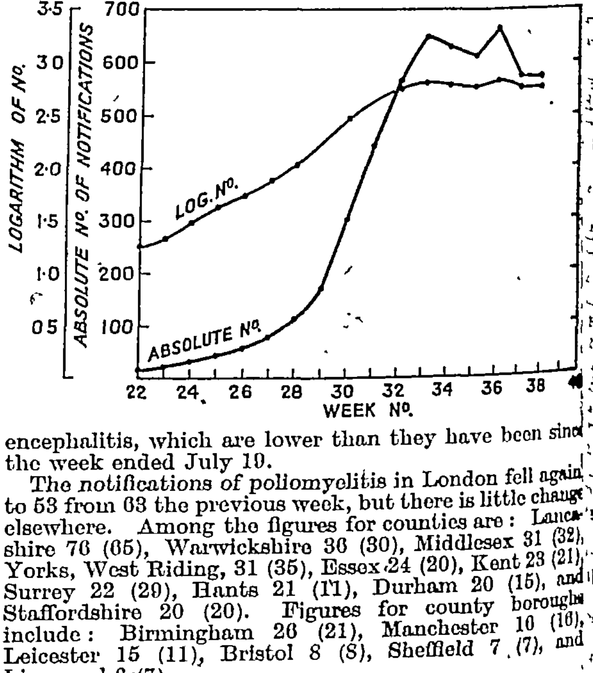
It is evident therefore that this outbreak was due to the infection of a dairy cow. The animal presumably developed septicæmia as a complication of enteritis; and since her milk was added to that of the other cows the whole supply was infected.

Cholera in Egypt

Cholera broke out in Egypt about Sept. 22; and over a hundred new cases are now being identified each day; but up to the beginning of this week Cairo was still free from the infection. The *Times* reports vigorous countermeasures by the government: the opening of schools and universities in Cairo and Alexandria has been postponed, and public gatherings are forbidden; the movement of people out of the infected areas has been stopped. The whole population is to be inoculated with anti-cholera vaccine, supplies of which have been obtained from Britain, the United States, and South Africa; public vaccination was to start last Wednesday. The government has offered a reward of £E.1000 for information about black-marketeers, *who charge £E.5 for each injection.* Passengers leaving this country for Egypt are now required to undergo vaccination against cholera. It is not yet known whether any special investigations are planned by the Egyptian authorities; epidemiologists have for some time been pressing for a controlled study of the sulpha drugs, and particularly of sulphamezathine, in this disease.

Poliomyelitis and Polioencephalitis

The number of notifications of poliomyelitis in England and Wales in the week ended Sept. 20 was 571 (572) and of polioencephalitis 23 (42). Figures in parentheses are those for the previous week. The most interesting feature is the sudden fall in notifications of polioencephalitis, which are lower than they have been since the week ended July 19.



The notifications of poliomyelitis in London fell again to 53 from 63 the previous week, but there is little change elsewhere. Among the figures for counties are: Lancashire 76 (65), Warwickshire 36 (30), Middlesex 31 (32), Yorks, West Riding, 31 (35), Essex 24 (20), Kent 23 (21), Surrey 22 (29), Hants 21 (11), Durham 20 (15), and Staffordshire 20 (20). Figures for county boroughs include: Birmingham 26 (21), Manchester 10 (16), Leicester 15 (11), Bristol 8 (8), Sheffield 7 (7), and Liverpool 6 (7).

Infectious Disease in England and Wales

WEEK ENDED SEPT. 20

Notifications.—Smallpox, 0; scarlet fever, 805; whooping-cough, 1378; diphtheria, 189; paratyphoid, 23; typhoid, 16; measles (excluding rubella), 1066; pneumonia (primary or influenzal), 252; cerebrospinal fever, 35; poliomyelitis, 571; polioencephalitis, 23; encephalitis lethargica, 3; dysentery, 100; puerperal pyrexia, 115; ophthalmia neonatorum, 55. No case of cholera, plague, or typhus was notified during the week.

Deaths.—In 126 great towns there were no deaths from enteric fever or scarlet fever, 2 (0) from measles, 2 (0) from diphtheria, 9 (0) from whooping-cough, 82 (4) from diarrhœa and enteritis under two years, and 1 (0) from influenza. The figures in parentheses are those for London itself.

The number of stillbirths notified during the week was 209 (corresponding to a rate of 24 per thousand total births), including 23 in *London*.

JECTION OF JOINTS WITH ACID POTASSIUM PHOSPHATE

SIR.—At the end of their letter on acid injection of nts (Sept. 20) Dr. Mandel and Dr. Nicolson mention need for physiotherapy to treat the associated ositis.

In my smaller series of cases, 60 hips and knees, the ositic condition has benefited by concurrent injections the myalgic spots with 'Novocain,' but the great d has been for re-education in posture and walking d above all redevelopment of wasted muscles.

It is usually reported that wasting occurs regularly y in osteoarthritis of the hip-joint; but patients with ir knee-joints affected have commonly remarked that, en the pain has diminished and the mobility increased, joint "feels as if it is giving way"; and their driceps are found to be very weak.

When practicable all acid injection cases which have wn marked improvement—about 60%—are sent to rehabilitation department for strenuous non-weight-ring exercises and for the correction of such ormities as may have arisen; and emphasis is laid the importance of doing such exercises at home for periods every day. The necessity of restoring muscle er and correcting posture cannot be overstated. genu valgum, scoliosis, and the ordinary hip flexion ormity are left untreated much of the improvement ed is lost.

ck. EDWARD S. VERGETTE.

SOCIAL MEDICINE

SIR,—Dr. Beryl Harding's letter (Sept. 27) might well onsidered in connexion with a letter from Miss Amy le, chairman of the Women Public Health Officers' ciation, which appeared in the *Times* of Sept. 12.

Dr. Harding wants there to be available to the general ctitioner "a service of voluntary workers, or part-e paid workers . . . *under trained supervision* . . . to e effect to the G.P.'s instructions . . . more especially re cases need handling in terms of hygiene."

I wonder whether Dr. Harding would agree with s Sayle that "in the future the health visitor will the generalised medical social worker for the whole ulation." If this were accepted the health visitor ll surely supply "the trained supervision to give ct to the G.P.'s instructions." The fact that Dr. rding does not automatically turn to the health itor to provide the service required seems to indicate t she visualises a function the health visitor of today not able to fulfil. It cannot be disputed that her mary function is to advise and teach the laws of healthy ng. She is par excellence the health worker in the al setting, but she is not the social worker in the lth setting. It could well be argued that this consti-es the fundamental difference between the health itor and the almoner. At present there does, however, ear to be a no-man's-land untouched by either pro-sion, and the indications are that the whole subject the functions of the various workers in the health m still requires considerable thought and clarification.

stitute of Almoners,
London, W.C.1.

MARJORIE STEEL
Secretary.

MORE STONES FOR OUR GLASS HOUSE

SIR,—It is customary, when a new term is introduced o medicine or an allied science, that it should be ived from a dead language (or sometimes, regrettably, m a combination of dead languages). Unfortunately, ds are not always chosen with the care used by the Sir Arthur Hurst when he coined the term chalasia."

Two examples come to mind. Fallot's tetralogy is y much in the news now; but a "tetralogy," accord-to the *Concise Oxford Dictionary*, is "a group of four matic or operatic works, esp. three tragedies and a yric drama." The word "tetrad" would surely be re correct, and Fallot would then be brought into line th Hutchinson and Charcot. The other example is halassæmia," an alternative name for Mediterranean æmia. This word might be taken to mean "a condition which the blood resembles the sea"; and if it thought necessary to have a Greek-derived alternative for a disease which already has two names, "thalassanæmia" might be a better choice.

Both these forms are given in medical dictionaries: but it is hardly to be expected that words well established by usage will be displaced. It is just as well to be aware, however, that some of the terms we use should not really have the meanings we give them.

London, W.10. KEITH LOVEL.

HORMONE TREATMENT BY IMPLANTING PELLETS

SIR,—As a historical footnote to your annotation of Sept. 27, it is perhaps worth pointing out that subcutaneous implantation of pellets is not, as has generally been assumed, a new method, although its application with the object of prolonging the action of the implanted substance is new.

In 1861 G.-V. Lafargue,[1] of St. Emilion, published details of a method which he described as "inoculation hypodermique par enchevillement" (cheville = plug or pellet), in which the skin was punctured obliquely to a depth of 60–70 mm. with a darning needle and a pellet of morphine or other drug was inserted into the subcutaneous tissue through the puncture, which was sealed with collodion or stamp-paper. Lafargue also described the use of a "dry syringe," which was a crude injector or implantation-gun.

Bruns[2] in 1869 published particulars of a greatly improved instrument which he described as an "Implantationsnadel." This was used for the implantation of various drugs in the form of pellets, for which Bruns proposed the name "Bacilli medicamentosi."

A fuller discussion of the origins of this and other forms of hypodermic medication will be found in a study[3] I have recently published.

Pound Hill, Sussex. N. HOWARD-JONES.

PRIVATE WARDS IN HOLLAND

SIR,—In connexion with your article (Sept. 6) on treatment in private wards under the National Health Service, our experiences in the Netherlands may be of some interest.

Here there are hardly any nursing-homes. Some hospitals, mostly university clinics, have ordinary wards only; most hospitals contain ordinary wards, small wards, and single rooms. These different wards and rooms are indicated by "classes," as on the railways. Third class is the ordinary ward (with 12–20 beds in old-fashioned and 6–8 beds in more modern hospitals); "second class B" or "middle class" is a small ward (with 3–4 beds); "second class A" or "second class" is a room with 2 beds; while first class is a single, one-bedded room.

Over here only a small minority of the patients have free hospital nursing and treatment. A minority in the third class pays its own costs and is not insured; the great majority of the patients in ordinary wards are insured for the costs of nursing and treatment by a national insurance scheme which is compulsory for all employees earning a salary below an amount specified by law (the premium varying with the salary and half being paid by the employer). All others with an income less than this specified amount can voluntarily join this national scheme, under which doctors' fees are also paid. Those with higher incomes can, of course, join private insurance schemes.

Patients who wish to be nursed in a second-class ward or room, or in a single room, pay the hospital and their doctor privately. If they are insured under the national scheme they pay the difference between the rates under the insurance system and the private (second- or first-class) rates. Second- and first-class rates are normally fixed so that the full maintenance costs are covered. Nowadays this is not always the case with class 2B rates, since prices have risen so much; but the rates charged to classes 2A and 1 provide a surplus which is devoted to the needs of the hospital as a whole; and this surplus helps to make up the financial deficit from the running of the ordinary wards.

Letters to the Editor

THE CLINICAL PATHOLOGIST

SIR,—As chairman of the Association of Clinical Pathologists' committee on training of clinical pathologists, I should like to comment on your leading article of Sept. 20. I confine my remarks entirely to the matter of training and qualification.

During the past few years the development of laboratory methods in medicine has created a vast and growing demand for such workers in hospitals: the demand has greatly exceeded the supply, and a number of appointments have been made of individuals who have had quite inadequate clinical and laboratory training. This has been a matter of serious concern to the Association of Clinical Pathologists, and it was decided, as a matter of urgency, to lay down some broad outlines of training suitable for hospital pathologists.

As your leading article rightly states, three years' laboratory experience suffices only to give a general grounding in medical laboratory work. The individual will further develop his specialty during the last year of his five years' training and subsequently. However desirable a longer period of training may be in theory, in practice five years' post-registration training is as much as can reasonably be asked of candidates at present. There is no ideal higher examination for pathologists: probably the best is the M.D. (Path.) of the University of London, but this is only available to London graduates. As regards the M.R.C.P., it may be that one year's clinical experience by itself is inadequate, although the Royal College of Physicians' committee on neurology recommended that all budding neurologists should obtain the M.R.C.P. *during* or at the end of the 18 months' period of general medical training, and in practice a fair number of candidates do obtain the M.R.C.P. only one year after graduation. In the case of the trainee clinical pathologist, much of his experience subsequent to the year's clinical appointment has a definite clinical bearing, and covers some of the ground demanded by the M.R.C.P. examination.

Your article is in error in implying that a higher medical qualification is practicable only for a few leaders of the profession. At the present time 50% of the members of the Association of Clinical Pathologists hold one or more higher medical qualifications, and nearly 25% possess the F.R.C.P. or M.R.C.P.; in addition, many hold science degrees or diplomas such as the D.P.H. and D.T.M. It is already the custom in a number of laboratories to encourage the junior members of the staff to acquire an M.R.C.P. at the earliest opportunity.

It may be that eventually a special examination will be the solution; and this is under consideration by the committee at the present time. Until such a special qualification has been worked out, it is surely desirable that trainees should be encouraged to take, if possible, one of the existing higher examinations.

London, S.E.13. E. N. ALLOTT.

SIR,—In your leading article the question is asked: "How came it that the clinical pathologist undertook to combine the diverse techniques of all four laboratories?" No-one conversant with the history of pathology in this country could have asked such a question, since it is the separation of the four laboratories that is the new departure; at least, the separation of bacteriology from morbid anatomy and the appearance of hæmatology as an independent culture. Biochemistry is a child of the present generation; it was no more than an embryo till 1920 or later.

We clinical pathologists can claim to carry on the English tradition of pathology—i.e., the cultivation of the science as a whole in its relation to clinical medicine. We are not "a new genus of less highly differentiated specialist" but rather we follow the lead of great British pathologists such as Robert Muir, A. E. Boycott, and many others who contributed to all branches of pathology. Even in the academic field this tradition persists, for there are still many chairs "of pathology" in the wider sense. An arrangement of this kind at Oxford enabled Sir Howard Florey, a pure histopathologist, to concentrate the energies of his department on the preparation of penicillin.

Nor is there anything new in hospital pathologists having care of patients. In fact this was the original arrangement in most London hospitals, and till very recently it was widespread in the smaller provincial hospitals. My father was honorary pathologist and assistant physician at St. Thomas's Hospital before he was given the then combined chairs of pathology and clinical medicine at Edinburgh; and at Moorfields and other special hospitals in London the post of pathologist was held till very recently by aspirants to the clinical staff.

The teaching hospitals in London are still divided as to their preference. Some have a clinical laboratory under the charge of a clinical pathologist; others have separate laboratories for each branch of pathology. The London Hospital and University College Hospital have had clinical pathologists for a quarter of a century, in addition to special departments under professorial staff. There is much to be said for this arrangement. It provides a training on a broad basis for young pathologists; it works for close liaison between the clinician and the laboratory whence he obtains many of the data he needs for diagnosis; and it ensures that a single specimen of, for example, cerebrospinal fluid is examined as a whole by a pathologist who knows something of the clinical side of the case, instead of being sent to one laboratory for cytology, to another for chemistry, to a third for bacteriology, and perhaps to a fourth for serology. (This is no fantasy. I am told that cerebrospinal fluids are examined in this piecemeal fashion in at least one teaching hospital in London.)

The aim of clinical pathology is to bring the facilities of the pathological laboratory into the closest possible relation to the hospital patient. The clinical laboratory is the old "side-room" enlarged and improved to cope with the advances of medical science. The goal of the clinical pathologist is primarily the diagnosis of disease and the control of treatment; but in carrying out this utilitarian task he gains a broader knowledge of the natural history of diseases than is possible for any worker in an isolated department, and so makes his own special contribution to the progress of medicine.

National Hospital, Queen Square,
London, W.C.1.
J. G. GREENFIELD.

ORIGIN OF CEREBRAL SURGERY

SIR,—In your leading article of Sept. 20 on Cushing you state that: "Cerebral surgery started in London at the National Hospital, Queen Square, and Victor Horsley . . . must always be regarded as its *founder*." This does less than justice to the Maida Vale Hospital for Nervous Diseases, in those far-off days known as the Hospital for Epilepsy and Paralysis, and located in Portland Terrace, Regent's Park.

Memories in these crowded days are short; but reference to the back numbers of THE LANCET, 1934, ii, 715, 1062, 1207, and 1255 will recall the fact that a big dinner was held at the Dorchester Hotel on Nov. 29, 1934, with Lord Horder in the chair, to celebrate the jubilee of the first removal by operation of a cerebral tumour, a glioma, by Rickman Godlee, on Nov. 27, 1884. This tumour had been accurately diagnosed and localised by Hughes Bennett, physician to the hospital; the man lived for four weeks, and would probably have survived but for infection of the wound, with subsequent meningitis.

It is, perhaps, worth recalling that both Hughlings Jackson and David Ferrier were present at the operation; and you rightly mentioned in your article that the work of these two famous men instigated the development of intracranial surgery. It was not Sir Victor Horsley, however, but Sir Rickman Godlee who first operated for cerebral tumour.

At the jubilee dinner was Sir James Crichton-Browne, who, over sixty years previously, when head of the West Riding Asylum, had encouraged Ferrier to do his original work in the laboratories at the asylum. Many of the National Hospital physicians were *also* present at the dinner. At the Royal Society of Medicine, before the dinner, Wilfred Trotter, F.R.S., gave an address on the subject, entitled A Landmark in Neurology, which THE LANCET published on Dec. 1, 1934.

London, W.1. WILFRED HARRIS.

5 g. of sulphadiazine daily for five days, without effect he fever. Right nephrectomy was therefore undertaken une 17. A tumour about 2 inches in diameter was found te upper pole of the kidney and this was identified oscopically as a hypernephroma.

nce the second day after operation this man's perature has not risen above normal. On Aug. 20, months after operation, the E.S.R. was only 16 mm. hr. The patient had gained 2 stone in weight and back at work.

usalem. BENJAMIN DOLL.

Obituary

JOHN CROSTHWAITE BRIDGE

C.B.E., M.R.C.P.E., F.R.C.S.E., D.P.H.

r. J. C. Bridge, consulting medical officer to Imperial nical Industries and formerly H.M. senior medical ector of factories, died at his home at Worthing on . 27. He was a notable pioneer in industrial medicine his wise counsel will be missed in the difficult times d.

Press Portrait

orn in Essex on June 5, 1877, the son of the Rev. es Henry Bridge, he was educated at Carlisle mmar School and at Middlesex Hospital to which was awarded an entrance exhibition. He took the Conjoint diploma in 1902; the D.P.H. (Camb.) in 1906; the F.R.C.S.E. in 1910; and the M.R.C.P.E. in 1920. He was also a barrister-at-law of the Middle Temple, having been called in 1913. Early in his career he became interested in preventive medicine, and at the Carnegie Institute, Dunfermline, he was a pioneer in the medical examination of schoolchildren. Later he served as assistant M.O.H. for the county borough of Devonport and as M.O.H. for Breconshire. In January, 1914, he entered the Home Office as Medical Inspector of Factories under Sir Thomas Legge, and thus with E. L. Collis, became one of a triumvirate whose rk is appreciated both in this country and abroad. 1927 Bridge succeeded Legge as Senior Medical pector and he held this post until he retired in 1942. that occasion we wrote: "*for the past 44 years the eption and development of industrial medicine in s country has been directed by two outstanding blic servants. The present intense and widespread erest in the health of the industrial worker and in upational medicine is a tribute to the soundness of foundations which these pioneers have laid.*"

It is not easy to assess Bridge's work because he did in an unobtrusive and disarming way, and his name not associated with any special subject. He took s credit than was his due for any progress made by staff. He used to disclaim any special knowledge scientific subjects, but he had a flair for picking out e essentials of any complicated problem, whether entific, legal, or clinical; and his modesty covered unrivalled knowledge of industrial and occupational alth matters. During his term of office the number of edical inspectors increased and the subjects dealt th became more complex. Bridge took all difficulties his stride and guided his staff with an easy and friendly cipline; the affection with which they regarded him re witness to his qualities as a chief. If good administration can be defined as a capacity for getting things one in the most sensible way and in drawing the best om one's colleagues, then Bridge was an ideal administrator. His capacity for listening, together with his gal training and prodigious memory, made him an cellent chairman of committees.

He was chairman of the Institute of Professional Civil Servants from 1922 to 1926 and again in 1930–31, and he played an important part in building the institution up to its present strength. After he retired from the Factory Department he became chairman of the Association of Industrial Medical Officers. He was a member of many committees, including the Industrial Pulmonary Diseases Committee and the Industrial Solvents Committee of the Medical Research Council; the Ministry of Health Committee on Cancer; the Prevention of Blindness Committee, and the various other departmental committees in connexion with workmen's compensation, silicosis, pneumoconiosis, and anthrax. In the international field he was a member of the International Correspondence Committee of the I.L.O. and of the Commission Internationale Permanente pour la Médecine du Travail. His work at Geneva kept him in touch with all that was happening in industrial medicine throughout the world and his reputation was deservedly international.

Bridge was made C.B.E. in 1934, and from 1937 to 1941 he was hon. physician to the King.

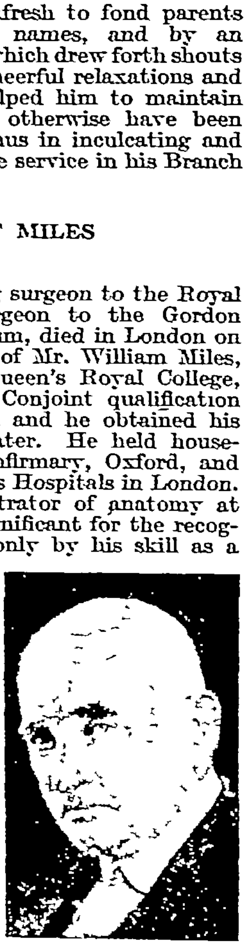
He married in 1904 Bessie, daughter of Gateward Coleridge Davies. She died in 1933 and in 1935 he married Joan, daughter of James S. Hann, of Finchley.

J. M. D. writes: "Bridge was above all a good colleague, and his first casual introductions of a new junior as 'my colleague' did much to implant in the newcomer a lasting sense of fellowship and corporate responsibility. Nor did he limit his interest to his younger colleagues at work; their wives and families too were equally his concern, and he was at his best in their homes. There he was wont to endear himself afresh to fond parents by remembering the childrens' names, and by an unexpected capacity for capering which drew forth shouts of glee from youngsters. These cheerful relaxations and a generosity in sharing credit helped him to maintain easily a discipline which might otherwise have been irksome, and Bridge succeeded thus in inculcating and fostering a team spirit which made service in his Branch a recognised privilege."

WILLIAM ERNEST MILES

F.R.C.S.

Mr. W. Ernest Miles, consulting surgeon to the Royal Cancer Hospital and senior surgeon to the Gordon Hospital for Diseases of the Rectum, died in London on Sept. 24. Born in 1869 the son of Mr. William Miles, B.A., J.P., he was educated at Queen's Royal College, Trinidad. In 1891 he took the Conjoint qualification from St. Bartholomew's Hospital and he obtained his surgical fellowship three years later. He held house-appointments at the Radcliffe Infirmary, Oxford, and at the Metropolitan and St. Mark's Hospitals in London. Till 1899 he was also a demonstrator of anatomy at Bart's, an interest which was significant for the recognition he was later to win not only by his skill as a surgeon, but also by his outstanding researches in the spread of cancer of the large intestine and rectum. Writing of this work, which Miles in 1923 embodied in his Lettsomian lectures, C. E. D. writes:



Janet Jevons

"When planning an operation for the eradication of any form of malignant disease the surgeon has first to take stock of all possible paths of lymphatic spread. This was accomplished for the rectum by the pioneer work of Mr. Ernest Miles. He gave a detailed description of the rectal lymphatics, describing them as arranged in three groups—intramural, intermediary, and extramural. He pointed out that the main direction of lymphatic drainage was upwards by efferents accompanying the superior hæmorrhoidal vessels to drain into lymphatic glands along the main trunk of the superior

In Dutch hospitals ordinary wards and private wards (small wards and single rooms) have been incorporated for some decades in the same hospitals. The ordinary wards have *isolation rooms* in which third-class patients are nursed, when need be, without extra charge. The private rooms (classes 2A and 1) are separated from each other only if separation is medically indicated (for instance in separate departments for medical and surgical diseases), and they are never placed in the ordinary ward units or blocks but are grouped together in separate units; and it is the same with the small wards (class 2B).

It should be explained that the nursing and medical attention are exactly the same in the ordinary wards as in the small wards or single rooms. Units of single- or two-bedded rooms have relatively more nurses, but only because these are less economical than larger wards: a decreasing number of beds in a ward or room means an increasing nurse-bed ratio.

Why, then, do patients wish to be accommodated in small wards or single rooms? For three reasons: (1) greater privacy, (2) better catering, and (3) longer and more visiting hours. Points (1) and (3) are most important to the patients.

Experience has proved the awkwardness of mixing classes. In particular, the difference in visiting hours gives rise to jealousy among the patients nursed in the ordinary wards. Moreover, nursing supervision and administration is difficult.

The idea of making no distinction, save any that is medically indicated, in nursing attention is a fine one; but in our country I fear it is impracticable at this time, since the deficits of the private hospitals are not covered by the public treasury; third-class rates do not meet costs, and the hospitals need the financial surplus derived from first- and second-class accommodation. There is a very strong feeling in the Netherlands against privately owned nursing-homes, run as a business enterprise, for the nursing of the wealthier patients: we prefer that all should enter hospital. In our experience, however, it is necessary to group ordinary wards, small wards, and single rooms in separate blocks or nursing units; and this separation does not impede administration.

J. C. J. BURKENS
Medical Director.

Diaconess Hospital, Meppel, Holland.

CALCIFEROL IN PULMONARY TUBERCULOSIS

SIR,—I read with great interest Dr. Phelan's letter (May 31) quoting certain of my publications, following the article by Dr. Feeny, Dr. Sandiland, and Dr. Franklin, published on April 5. I should like in a few words to indicate my view of the present status of calciferol in pulmonary tuberculosis of adults.

1. My first two publications with Bachet[1] concerned patients who had been severely undernourished and were in a grave state of nutritional deficiency. Vitamin-calcium therapy had, in these subjects, a manifest action in slowing down the evolutionary process; almost all of them had very advanced tuberculosis, apparently beyond therapeutic reach, which incited us to try this medication; it proved very useful for them.

2. More recent trials in tuberculous patients who had not undergone severe dietary restrictions have not afforded such encouraging results; and some are disappointing. This group presented toxic signs more quickly; thus they had to be given smaller doses than the first group. However, insufficient time has elapsed to draw conclusions.

3. Dosage is still undefined; but in any case it seems reasonable to avoid the appearance of toxic symptoms. There is *amazing variation in tolerance*, perhaps owing to variations in the previous state of vitaminisation in vitamin D_2.

4. It appears that calciferol preparations used on the Continent are better tolerated than certain similar British products, which cause intoxication with smaller doses.

5. Our work, clinical as well as experimental in the dog, has already enabled us to state that the intramuscular route does not entail intoxication.[2] No hypercalcæmia or hyperazotæmia is noticed, even with extremely high doses, there any clinical, digestive, renal, or general but it remains to be seen if, corresponding to this better tolerance, the parenteral route does not entail loss of therapeutic efficacy.

6. It is important to pursue the study of calciferol in pulmonary tuberculosis of adults. This can be justified by the proved efficacy of calciferol in certain types of extrapulmonary tuberculosis—for example, lupus, other cu forms, and serous tuberculosis. In 1930 Meerseman[3] stressed the importance of vitamin D in the treatment of experimental tuberculosis *in the guineapig*; *in guineapigs* which were infected with tuberculosis and were at the same time calciferol, a remarkable proportion did not develop clinical tuberculosis; whereas in a control series, without vitamin therapy, all the animals died. Levaditi and Li Yan Po showed that irradiated ergosterol produced in the rabbit an elective calcium precipitation at the point of bacillary infection; and, according to Raab,[5] cultures of tubercle bacilli do not grow but degenerate in the presence of calciferol. The impressive array of clinical and experimental results call for further investigations.

7. Other questions remain unanswered. Does addition of calcium facilitate, as suggested by some authors, the appearance of signs of intoxication, in the same way as in the animal? Should vitamin A, held by many to act as an antagonist to vitamin D_2, be utilised as a regulator?

Finally, it should be emphasised that these studies must never oust or delay the application of classical methods, such as collapse therapy, whose value has been proved.

Centre de Recherches de
l'Hôpital Foch, Paris.

HUGUES GOUN

ABUSE OF THE EMERGENCY BED SERVICE

SIR,—I should like to put on record two examp cases which we have been receiving from doctors th the Emergency Bed Service.

The first was a man who arrived with an unintell note which when deciphered said that he was suff from acute appendicitis and required admission. details of any clinical findings were included in the On examination of the patient it was quite app that the doctor had not examined him previously had no symptom and bore not a single sign of "emergency" condition from which he was report have been suffering.

The second was a case which I accepted at the morning. According to the doctor the patient suffering from severe vomiting through food-poi and was in a state of collapse. Preparations were to admit her and carry out emergency treatment, bu when she arrived she felt perfectly well. Furthermor *it transpired that she had not even been seen by th* doctor concerned, and all the arrangements had bee made over the telephone.

The Emergency Bed Service is an excellent organisation, and I feel it is a pity that unfair advantage taken of it by a certain section of the profession.

R. S. KAGAN
Resident Medical Officer.

Westminster Hospital,
London, S.W.1.

SEDIMENTATION-RATE IN HYPERNEPHROMA

SIR,—The article by Dr. Catlin, Mr. Bintcliffe, an Dr. Marson in your issue of Aug. 2 prompts me to recor the following case.

A man, aged 42, came under treatment for tonsillitis an maxillary sinusitis in November, 1945. The erythrocyte-sedimentation rate (E.S.R.) was 47 mm. in 1 hr. (Westergren When treatment was completed he was kept under observatio since the E.S.R. remained high, *ranging* from 47 mm. up t 110 mm. in 1 hr.

Sixteen months after he was first seen he began to complai of tiredness, and he was observed to be mildly pyrexial in th evenings. The hæmoglobin was 75%, and red-cell coun 3,900,000 per c.mm. The evening pyrexia continued, and tw months later intravenous pyelography showed compressio of the calyces of the right kidney. The patient was treat

hæmorrhoidal artery and beyond this to the inferior mesenteric and aortic glands. Mr. Miles planned the abdominoperineal operation in 1906 and began to employ it in the following year. He took this step because he was convinced that the tissues of the upward zone of spread lay beyond the reach of any operation carried out solely from the perineum. He pointed out that when the perineal route is employed it is seldom possible to reach the glands situated above the bifurcation of the superior hæmorrhoidal vessels yet glandular spread may have extended higher than this. The chief merit of the abdominoperineal operation (and similar combined operations such as the perineo-abdominal and synchronous combined operation) is that they permit the removal of glands at a higher level than is possible by perineal excision. The new operation introduced by Miles forty years ago extended the scope of surgery in the treatment of rectal cancer and brought a prospect of cure to some patients who could not have been cured by earlier surgical procedures." One of his colleagues relates that only a few weeks ago he saw a patient operated upon by Mr. Miles in 1939 who showed no evidence of recurrence anywhere. With D. H. Goodsall, he collaborated in the publication of *Diseases of the Anus and Rectum*, a standard work in proctology, which Miles himself later rewrote and enlarged.

Miles's work in London was interrupted by the first world war, and he served in France and Belgium from 1914 to 1919, latterly as senior surgeon and commandant of an Allied Forces base hospital and consulting surgeon to the Etaples area. On demobilisation he returned to the Royal Cancer Hospital where he collected round him a team of brilliant young men some of whom have unfortunately predeceased him—Cecil Jóll, Jocelyn Swan, and Cecil Rowntree.

"To see Miles at work with his assistants," writes M. S., "was to see British surgery at its best. There was a calm, unhurried atmosphere about the theatre, and the leisurely manner in which he went about his work made the whole performance seem at first somewhat slow. This was deceptive, of course, for there was an economy of movement and an effortless ease which only skill and experience could bring about. There was *no delay, no hitch*, everything looked simple, and the operation moved on quietly to its close. A glance at the clock showed that it had all taken place in an incredibly short space of time—in fact, as Lord Moynihan remarked, 'the clock stood still.' And after it all there was the chat about the operation, the cup of tea and the cigarette; all very friendly, for Miles was the most approachable of men, and was kindness itself to visiting surgeons and students."

At home his abilities were recognised by many appointments apart from his hospital ones. He was consulting surgeon to the Army, a member of the National Radium Commission, the British Empire Cancer Campaign and the editorial committee of the *British Journal of Surgery*. The abdominoperineal operation brought him fame and honorary fellowships from many countries—America, France, Ireland, and only a few weeks ago Greece. The fellowship of the Irish college specially appealed to him for on his mother's side he was of Irish descent. Another tribute which pleased him was the present and letter which reached him on his last birthday from the members of the staff of St. Mark's Hospital, "wishing him every happiness in his retirement, acknowledging him as a great friend and a trusted leader in their specialty." As a young man he had excelled at tennis, and in later years he enjoyed golf, but racing was his favourite relaxation and nothing pleased him more than to entertain his friends in his box at Ascot. "The Gordon Hospital," writes P. D., "largely through Mr. Miles's capacity and teaching, attained a wide popularity, especially in the United States, and year by year American proctologists and other postgraduates visited the hospital and attended its lectures. Miles was a general surgeon besides being a proctologist, but in time he became almost entirely occupied by his specialty and the treatment of cancer in general. A man of outspoken convictions he made great friendships and I believe, strong enmities, but in his latter years he attained great and lasting happiness."

Mr. Lawrence Abel writes: "Miles performed the first abdominoperineal operation for cancer of the rectum more than forty years ago, and survived one of his earliest cases by a few months. The Miles operation was soon known throughout the world, and has stood the test of time; today with little or no modifications it is the operation of choice for rectal cancer in the vast majority of surgical centres. So long as cancer of the rectum can only be cured by the surgeon, will Miles's name be honoured for the pioneer work he did and for the firm foundation of pathology and splendid superstructure of finished technique which he has bequeathed to humanity. He has also left us the operation of recto-sigmoidectomy for complete procedentia of the rectum and a classic work on fistula, which well repays reading at frequent intervals.

"He loved life, men, and horses, a good meal, good company, and a merry story. His annual box at Ascot was a joyous institution for friends and old patients who so often became his friends. I have seen as many as seven men, whose rectums he had removed, enjoy his hospitality together, not knowing what the others owed to their host."

Mr. Miles is survived by his widow, formerly Miss Janet Loxton, whom he married in 1944.

CHARLES PAGET LAPAGE

M.D. MANC., F.R.C.P.

PÆDIATRICS generally and Manchester especially are the poorer for the loss of Dr. Lapage who died at his home in Didsbury on Sept. 23 in his 69th year after an illness of a few weeks. He came of a Yorkshire family and was born at Nantwich, where his father, Dr. Charles Clement Lapage, had settled in practice. The family is also represented in medicine by his brother, Dr. Geoffrey Lapage, an eminent zoologist.

Lapage was educated at Epsom College and Manchester University, and after qualification in 1902 he became house surgeon under William Thorburn at the Manchester Royal Infirmary. From that time he devoted himself to children's diseases, beginning as resident medical officer at the Pendlebury Children's Hospital to which he was attached practically for the rest of his life. In 1912 he was appointed physician to the hospital and in 1913 lecturer, and later reader, in diseases of children in Manchester University, a post which he held till shortly before his death. In 1922 he was also appointed physician for children to St. Mary's Hospitals, Manchester, and in the same year he was elected F.R.C.P.

Lafayette

In children's work perhaps his greatest interest was in the mental side of disease and his book on *Feeble-mindedness in Children of School Age* is a standard work. He was associated too with all the local societies by which these diseases are cared for. Erythroderma was another disease which he helped to expound, and as a hobby he studied the ethics of medicine, on which he wrote several papers.

In 1903 it was written of him that he had "an insatiable love of athletics," and he remained a man of many interests and of a strenuous nature. All that he took up he did with a will and carried through; in fact his friends warned him in later life that he was not slacking off with increase of age as he deserved to do. In earlier days rugby football and running, in both of which he excelled, and in which he represented his university, were his athletic interests. Later in life long walks and runs to keep himself fit were not neglected. An energetic volunteer and territorial, he was mentioned in despatches during his service as a major in the R.A.M.C. during the 1914–18 war. Dr. Lapage leaves his widow with two sons and a daughter, and a third son died on active service in 1941.

Notes and News

HE POSSIBILITIES OF A MEDICAL EDUCATION

DESPITE all the fears for our liberty, so often voiced of years, Prof. Ida Mann, in her inaugural address for the ion 1947-48 of the Royal Free Hospital School of Medicine Sept. 26, saw medicine as offering one of the freest lives r to be lived in an overplanned world. Doctors can prac- equally well at the poles or the equator, among men, en, or children, or all three, in town or country, and in eral medicine or in a special branch. The curriculum, nded primarily to turn out good general practitioners, y or may not be fitted to its purpose, and is now being ely reconsidered. Some have suggested that the course uld early diverge into two curricula, students intending become laboratory workers following one course, and e intending to become clinicians another. This idea is alistic, she feels, because no-one can tell until he has a medical education what he is going to do with it; for the same reason she thinks it unwise to give scholar- which tie the scholar to any given branch. She believes the overlapping of the various subjects in the curriculum uld be taught with more imagination, and that students uld try to recognise and correlate the overlaps. As an mple, she gave the case of the graduate wishing to specialise phthalmology who has to relearn the pathways of rays gh a plus and a minus lens—knowledge gained in the s laboratory in his premedical years and since forgotten. medicine is an attempt to apply scientific method omplex biological problems, she said, no part of the lum is redundant.

NITRATE POISONING IN BABIES

he Belgian minister of public and family health has lated a warning to the effect that there have been several of cyanosis in babies from drinking a fairly large quantity well-water containing nitrate. This cyanosis does not ct breast-fed babies. People are advised not to use dered milk if the water for diluting it has to come from ell, and it is emphasised that the answer is breast-feeding. elles *Médical*, 1947, 27, 2036.)

"ONE SHILLING THE BOX"

[illegible] the outstanding characteristics of the present [illegible] increasing use of the euphemism—the "rodent minator" has acquired an almost national status; re has become natural organic fertiliser, which may be ed by the horticultural implement familiar to our pre- sors as the spade. So too the old familiar patent cine has graduated as a proprietary medicine and must join the masquerade under the title "household remedy." at least is the suggestion of the Proprietary Association Great Britain which has issued a brochure entitled *prietary Medicines—The Facts.* The association, however, its that it speaks for only 75% of the industry, so that re is still a considerable latitude for malpraxis among the aining manufacturers. The booklet states that 'pro- onal and domestic therapy now go hand in hand, and ntially are not in conflict, but actually allied," but this ement appears to ignore that the Penicillin Act has found way to the Statute Book and that the sulphonamides e been placed with the barbiturates in schedule 4 of the rmacy and Poisons Act. While the more blatant forms of vertising are no longer encountered, the Code of Standards Advertising Practice is almost naïve in its prohibition that the words 'cure' and 'heal' must not be used in con- ion with any skin complaint which can be considered as abnormal condition of the epidermal tissue, unless words h as 'promote' or 'promotes' be used in conjunction rowth." It is proved beyond doubt that proprietary dicines are produced under hygienic conditions and that redients of the highest standard are used in their prepara- n. While a prima-facie case is made out by the association some degree of self-medication and the association quotes the Report of the Select Committee issued in 1914 and wards from various sources to the 1941 Pharmacy and dicines Act, it ignores the recent report of the Pharma- tical Society on proprietary medicines. Perhaps it is ll difficult to find a rational justification for a competing, even ancillary, system of medication when the National lth Service comes into operation.

University of London

Dr. W. J. Hamilton, regius professor of anatomy in the University of Glasgow, has been appointed to the university chair of anatomy at Charing Cross Hospital medical school. Dr. G. W. Hayward has been appointed to the university readership in medicine at St. Bartholomew's Hospital medical college.

University of Sheffield

At recent examinations the following were successful:

Final Examination for M.B., Ch.B.—J. H. Blaskey, J. A. Chisholm, Elinor Dubas, Derek Hobson, A. H. Morris, J. B. Parkin, David Rider.

University of Leeds

Prof. Geoffrey Jefferson, F.R.S., will deliver the inaugural lecture of the faculty of medicine at the University Union at 3.30 P.M. on Thursday, Oct. 16. He is to speak on Scepsis Scientifica.

University of Edinburgh

Prof. N. Hamilton Fairley, F.R.S., will deliver the Cameron prize lecture for 1947 in the anatomy lecture theatre, University New Buildings, Teviot Place, Edinburgh, on Friday, Oct. 24, at 5 P.M. He will speak on Chemotherapy in Malaria.

University College, London

On Tuesday, Oct. 7, at 5 P.M., Prof. Ernst Hanhart of the University of Zürich will deliver the Galton lecture at the college, Gower Street, W.C.1. He has chosen as his subject Human Genetics with special reference to Deaf-mutism and Diabetes.

Charing Cross Hospital

At the prize-giving on Tuesday, Oct. 14, at 3.45 P.M., the Earl of Donoughmore will present the prizes. In view of the present crisis the annual dinner will not be held this year.

London Hospital

Owing to catering restrictions the annual old students dinner will not be held this year. The postgraduate course will also not take place.

St. George's Hospital

Dr. Anthony Feiling and Dr. Desmond Curran resumed their weekly neurological and psychiatric demonstrations on Thursday, Oct. 2, at 4.30 P.M., when Dr. Feiling gave a neurological lecture-demonstration. These demonstrations are open to doctors and senior students without fee.

National Hospital, Queen Square

Dr. Gordon Holmes, F.R.S., will give the introductory lecture for the autumn term at the medical school on Monday, Oct. 6, at 3.30 P.M. He will speak on Coördination of Movement and its Disorders.

Royal Dental Hospital, London

The clinical at home will be held at the hospital, 32, Leicester Square, W.C.2, on Saturday, Nov. 22. The annual dinner is not being held this year.

Sex Education Society

On Monday, Oct. 6, at 8 P.M., at Conway Hall, Red Lion Square, London, W.C.1, Dr. Norman Haire will speak on Marriage and Divorce.

Conference on Food and Drink Infections

On Thursday, Oct. 9, the Central Council for Health Education is holding a conference on this subject at Friends House, Euston Road, London, N.W.1. Lord Woolton will open the morning session at 10 A.M., and the other speakers will include Sir William Savage, Prof. G. S. Wilson, and Mr. L. H. Lampitt, D.SC. At the afternoon session, which will begin at 2 P.M., the speakers will be Dr. Robert Cruickshank and Dr. Robert Sutherland.

Beds for Streptomycin Treatment

The following hospitals have been added to the list of those hospitals (*Lancet*, Sept. 6, p. 360) at which cases of tuberculous meningitis and miliary tuberculosis may be received for treatment with streptomycin:—

The Queen Elizabeth Hospital, Birmingham (which takes adults; children are admitted to the Children's Hospital).
Hospital for Sick Children, Great Ormond Street, London, W.C.1.

The total number of beds for which streptomycin treatment is available for cases of tuberculous meningitis and miliary tuberculosis in the United Kingdom is still 150, the number for which supplies of the drug are at present available.

hæmorrhoidal artery and beyond this to the inferior mesenteric and aortic glands. Mr. Miles planned the abdominoperineal operation in 1906 and began to employ it in the following year. He took this step because he was convinced that the tissues of the upward zone of spread lay beyond the reach of any operation carried out solely from the perineum. He pointed out that when the perineal route is employed it is seldom possible to reach the glands situated above the bifurcation of the superior hæmorrhoidal vessels yet glandular spread may have extended higher than this. The chief merit of the abdominoperineal operation (and similar combined operations such as the perineo-abdominal and synchronous combined operation) is that they permit the removal of glands at a higher level than is possible by perineal excision. Notes and News

E POSSIBILITIES OF A MEDICAL EDUCATION

espite all the fears for our liberty, so often voiced of years, Prof. Ida Mann, in her inaugural address for the on 1947-48 of the Royal Free Hospital School of Medicine Sept. 26, saw medicine as offering one of the freest lives to be lived in an overplanned world. Doctors can prac- equally well at the poles or the equator, among men, en, or children, or all three, in town or country, and in al medicine or in a special branch. The curriculum, ded primarily to turn out good general practitioners, or may not be fitted to its purpose, and is now being ly reconsidered. Some have suggested that the course ld early diverge into two curricula, students intending ecome laboratory workers following one course, and e intending to become clinicians another. This idea is alistic, she feels, because no-one can tell until he has a medical education what he is going to do with it; for the same reason she thinks it unwise to give scholar- s which tie the scholar to any given branch. She believes the overlapping of the various subjects in the curriculum ld be taught with more imagination, and that students ld try to recognise and correlate the overlaps. As an ple, she gave the case of the graduate wishing to specialise phthalmology who has to relearn the pathways of rays ch a plus and a minus lens—knowledge gained in the ics laboratory in his premedical years and since forgotten. e medicine is an attempt to apply scientific method complex biological problems, she said, no part of the iculum is redundant.

NITRATE POISONING IN BABIES

E Belgian minister of public and family health has ated a warning to the effect that there have been several s of cyanosis in babies from drinking a fairly large quantity ell-water containing nitrate. This cyanosis does not ct breast-fed babies. People are advised not to use dered milk if the water for diluting it has to come from ll, and it is emphasised that the answer is breast-feeding. *alles Médical*, 1947, 27, 2036.)

"ONE SHILLING THE BOX"

the outstanding characteristics of the present is increasing use of the euphemism—the "rodent minator" has acquired an almost national status; ure has become natural organic fertiliser, which may be ed by the horticultural implement familiar to our pre- ssors as the spade. So too the old familiar patent icine has graduated as a proprietary medicine and must join the masquerade under the title "household remedy." s at least is the suggestion of the Proprietary Association Great Britain which has issued a brochure entitled *prietary Medicines—The Facts.* The association, however, its that it speaks for only 75% of the industry, so that re is still a considerable latitude for malpraxis among the aining manufacturers. The booklet states that "pro- sional and domestic therapy now go hand in hand, and tually are not in conflict, but actually allied," but this tement appears to ignore that the Penicillin Act has found way to the Statute Book and that the sulphonamides e been placed with the barbiturates in schedule 4 of the rmacy and Poisons Act. While the more blatant forms of ertising are no longer encountered, the Code of Standards Advertising Practice is almost naïve in its prohibition that e words 'cure' and 'heal' must not be used in con- ion with any skin complaint which can be considered as abnormal condition of the epidermal tissue, unless words h as 'promote' or 'promotes' be used in conjunction rewith." It is proved beyond doubt that proprietary dicines are produced under hygienic conditions and that redients of the highest standard are used in their prepara- n. While a prima-facie case is made out by the association some degree of self-medication and the association quotes m the Report of the Select Committee issued in 1914 and wards from various sources to the 1941 Pharmacy and dicines Act, it ignores the recent report of the Pharma- tical Society on proprietary medicines. Perhaps it is l difficult to find a rational justification for a competing, even ancillary, system of medication when the National alth Service comes into operation.

University of London

Dr. W. J. Hamilton, regius professor of anatomy in the University of Glasgow, has been appointed to the university chair of anatomy at Charing Cross Hospital medical school. Dr. G. W. Hayward has been appointed to the university readership in medicine at St. Bartholomew's Hospital medical college.

University of Sheffield

At recent examinations the following were successful:

Final Examination for M.B., Ch.B.—J. H. Blasker, J. A. Chisholm, Ellnor Dubas, Derek Hobson, A. H. Morris, J. B. Parkin, David Rider.

University of Leeds

Prof. Geoffrey Jefferson, F.R.S., will deliver the inaugural lecture of the faculty of medicine at the University Union at 3.30 P.M. on Thursday, Oct. 16. He is to speak on Scepsis Scientifica.

University of Edinburgh

Prof. N. Hamilton Fairley, F.R.S., will deliver the Cameron prize lecture for 1947 in the anatomy lecture theatre, University New Buildings, Teviot Place, Edinburgh, on Friday, Oct. 24, at 5 P.M. He will speak on Chemotherapy in Malaria.

University College, London

On Tuesday, Oct. 7, at 5 P.M., Prof. Ernst Hanhart of the University of Zürich will deliver the Galton lecture at the college, Gower Street, W.C.1. He has chosen as his subject Human Genetics with special reference to Deaf-mutism and Diabetes.

Charing Cross Hospital

At the prize-giving on Tuesday, Oct. 14, at 3.45 P.M., the Earl of Donoughmore will present the prizes. In view of the present crisis the annual dinner will not be held this year.

London Hospital

Owing to catering restrictions the annual old students dinner will not be held this year. The postgraduate course will also not take place.

St. George's Hospital

Dr. Anthony Feiling and Dr. Desmond Curran resumed their weekly neurological and psychiatric demonstrations on Thursday, Oct. 2, at 4.30 P.M., when Dr. Feiling gave a neurological lecture-demonstration. These demonstrations are open to doctors and senior students without fee.

National Hospital, Queen Square

Dr. Gordon Holmes, F.R.S., will give the introductory lecture for the autumn term at the medical school on Monday, Oct. 6, at 3.30 P.M. He will speak on Coördination of Movement and its Disorders.

Royal Dental Hospital, London

The clinical at home will be held at the hospital, 32, Leicester Square, W.C.2, on Saturday, Nov. 22. The annual dinner is not being held this year.

Sex Education Society

On Monday, Oct. 6, at 8 P.M., at Conway Hall, Red Lion Square, London, W.C.1, Dr. Norman Haire will speak on Marriage and Divorce.

Conference on Food and Drink Infections

On Thursday, Oct. 9, the Central Council for Health Education is holding a conference on this subject at Friends House, Euston Road, London, N.W.1. Lord Woolton will open the morning session at 10 A.M., and the other speakers will include Sir William Savage, Prof. G. S. Wilson, and Mr. L. H. Lampitt, D.SC. At the afternoon session, which will begin at 2 P.M., the speakers will be Dr. Robert Cruickshank and Dr. Robert Sutherland.

Beds for Streptomycin Treatment

The following hospitals have been added to the list of those hospitals (*Lancet*, Sept. 6, p. 360) at which cases of tuberculous meningitis and miliary tuberculosis may be received for treatment with streptomycin:—

The Queen Elizabeth Hospital, Birmingham (which takes adults; children are admitted to the Children's Hospital).
Hospital for Sick Children, Great Ormond Street, London, W.C.1.

The total number of beds for which streptomycin treatment is available for cases of *tuberculous* meningitis and miliary tuberculosis in the United Kingdom is still 150, the number for which supplies of the drug are at present available.

Ministry of Health

Mr. Aneurin Bevan, the Minister of Health, has appointed Mr. E. J. S. Clarke to be his private secretary.

Royal Appointment

Surgeon Rear-Admiral O. D. Brownfield, O.B.E., has been appointed an honorary physician to the King in place of the late Surgeon Rear-Admiral H. M. Whelan.

Regional Boards' Appointments

The following appointments as senior administrative officers of hospital boards have been made: *North-west Metropolitan region:* Dr. H. M. C. Macaulay (M.O.H. for Middlesex); *Leeds region:* Dr. A. B. Williamson (M.O.H., Portsmouth); *Welsh region:* Dr. A. T. Jones (medical officer, Welsh Board of Health).

Prospective Candidates

Dr. Charles Hill, secretary of the British Medical Association, has been chosen as prospective parliamentary candidate of the United Liberal and Conservative Association for Luton. Dr. J. W. Clegg, pathologist to the Brompton Hospital, has been adopted as prospective Liberal candidate for the Wells division of Somerset.

Award to Ministries

On Oct. 9 in Atlantic City, Sir Wilson Jameson, on behalf of the British Ministries of Food and Health, will accept an award from the American Public Health Association "for the war-induced programme of food distribution in Great Britain resulting in improved public-health standards there."

Diary of the Week

OCT. 5 TO 11

Monday, 6th

ROYAL COLLEGE OF SURGEONS, Lincoln's Inn Fields, W.C.2
5 P.M. Mr. N. R. Barrett: Neoplasms of the Lung.
6.15 P.M. Dr. H. J. Brennan: Endotracheal Anæsthesia.
ROYAL SOCIETY OF MEDICINE, 1, Wimpole Street, W.1
4.30 P.M. *Epidemiology and State Medicine.* Mr. K. I. Nissen: Poliomyelitis in St. Helena, 1945. Dr. L. M. Laurent: Acute Meningo-encephalitis of Undetermined Virus Ætiology.

Tuesday, 7th

ROYAL COLLEGE OF SURGEONS
5 P.M. Mr. A. Lawrence Abel: Surgery of the Œsophagus.
6.15 P.M. Dr. A. D. Marston: Pre-anæsthetic Treatment.
ROYAL SOCIETY OF MEDICINE
8.30 P.M. *Orthopædics.* Mr. George Perkins: Flat-foot or Instability of the Longitudinal Arch. (Presidential address.)
UNIVERSITY COLLEGE, Gower Street, W.C.1
5.15 P.M. Prof. J. Z. Young, F.R.S.: Structure of Peripheral Nerve and of Nerve-endings. (First lecture.)
CHADWICK LECTURE
2.30 P.M. (26, Portland Place, W.1.) Brigadier A. E. Richmond: Positive Health—its Attainment in the Soldier, and the Army's Contribution to it in the Civilian.
LONDON SCHOOL OF DERMATOLOGY, 5, Lisle Street, W.C.2
5 P.M. Dr. R. T. Brain: Congenital Abnormalities.

Wednesday, 8th

ROYAL COLLEGE OF SURGEONS
5 P.M. Dr. G. F. Rowbotham: Head Injuries.
6.15 P.M. Dr. C. Langton Hewer: Anæsthesia for Thoracic Surgery.
ROYAL SOCIETY OF MEDICINE
4.30 P.M. *Physical Medicine.* Dr. W. S. Tegner: Rheumatoid Arthritis. (Presidential address.)
UNIVERSITY COLLEGE
5 P.M. M. H. Pirenne, Dr. Sc. (Liége): Physiological Mechanisms of Vision. (First of six lectures.)
UNIVERSITY OF GLASGOW
8 P.M. (Department of Ophthalmology.) Prof. A. Lowenstein: Pathology and Clinical Aspects of Ocular Glass Membranes.

Thursday, 9th

ROYAL COLLEGE OF SURGEONS
5 P.M. Mr. A. M. A. Moore: Surgery of the Tendons.
6.15 P.M. Dr. T. Cecil Gray: *d*-Tubocurarine Chloride and its Use in Anæsthesia.
ROYAL SOCIETY OF MEDICINE
5 P.M. *Ophthalmology.* Dr. H. Arruga (Barcelona): Detachment of the Retina.
LONDON JEWISH HOSPITAL MEDICAL SOCIETY
3 P.M. (Woburn House, W.C.1.) Dr. Hugh Gainsborough: Presidential Address.
LONDON SCHOOL OF DERMATOLOGY
5 P.M. Dr. C. W. McKeeny: X-ray Technique.

Friday, 10th

ROYAL COLLEGE OF SURGEONS
5 P.M. Prof. J. R. Learmonth: Surgery of Portal Hypertension.
6.15 P.M. Dr. John Gillies: Volatile Anæsthetic Agents.
LEEDS AND WEST RIDING MEDICO-CHIRURGICAL SOCIETY
7.30 P.M. Dr. J. T. Ingram: Sir Jonathan Hutchinson, Dermatologist.

Appointments

ASHWIN, R. F., M.B. Camb., D.M.R.D.: asst. radiologist, York General Hospital and York County Hospital.
ELTON, ARNOLD, M.B. Lond., F.R.C.S.: surgical registrar, Ch Cross Hospital, London.
EMBERSON, G. A., M.A., M.D. Camb., M.R.C.P., D.C.H.: pædiat Royal West Sussex Hospital, Chichester.
GREGORY, I. L., M.B. Manc.: resident surgical officer, Bolton Infirmary.
HILL, R. L. T. M.B. Glasg.: radiologist, Hull Royal Infirmary.
HOCKEN, M. E., M.B. Glasg., D.P.H.: senior school M.O. and de M.O.H., Rotherham.
IMRIE, C. H., M.B. St. And., D.P.H.: asst. county M.O. and M East Suffolk.
JEWESBURY, E. C. O., M.A., D.M. Oxfd, M.R.C.P., D.P.M.: assistant, neurological department, St. Thomas's Ho London.
JUSTICE, J. J., B.SC., M.B. Glasg., D.P.M.: psychiatrist, D County Council.
MACKEITH, R. C., M.A., D.M. Oxfd, M.R.C.P., D.C.H.: assist the director of the department of pædiatrics, Guy's H medical school, London.
PATTINSON, HUGH, M.B. Edin., D.P.H.: asst. county M.O. district M.O.H., Hunts County Council.
PRITCHARD, P. V., M.D. Edin., F.R.C.P.E., D.P.H.: county co. Antrim.
WILSON, DONALD, M.B. Lond., M.R.C.P.: physician i.c. depart of physical medicine, Royal West Sussex Hospital, Chich Municipal Hospital of St. Richards, Chichester; War Mem Hospital, Bognor Regis; and Worthing Hospital.
WOOD, P. M., M.B. Edin., M.R.C.P.E., D.O.M.S.: ophthalmic surg Royal Halifax Infirmary.

County Borough of West Ham:

HINDEN, ELCHON, M.D. Camb., M.R.C.P.: pædiatrician.
LAWLESS, D. J., B.SC., M.B. N.U.I., D.P.H.: medical direc mass miniature radiography unit.

Lancashire County Council:

Asst. county M.O.H.:
BUCHANAN, M.B. Glasg., D.P.H.
COUPER, W. R. M., M.B. Edin., D.P.H.

Wrexham Emergency (County General) Hospital and Wrexham East Denbighshire War Memorial Hospital:

BARRACLOUGH, RONALD, M.B.E., M.B. Aberd., D.L.O.: asst. surgeon.
EVANS, P. R. C., C.M., M.D. Lond., M.R.C.P.: asst. physician.
FORBES, J. R., M.D. Lond., M.R.C.P.: physician.
WHITING, R. J., M.B. Lond., D.A.: anæsthetist.

Colonial Service:

MURLEY, J. R. P., M.R.C.S.: M.O., British Somaliland.
THORNTON, THOMAS, M.B. St. And., F.R.C.S.: surgeon special Palestine.

Births, Marriages, and Deaths

BIRTHS

ALLEN.—On Sept. 23, at Buckland Newton, Dorset, the wife Lieutenant Michael Allen, R.A.M.C.—a son.
HARRIS.—On Sept. 21, at Windsor, the wife of Dr. Cyril Har —a daughter.
HARWOOD.—On Sept. 19, at Carshalton, the wife of Dr. H. Harwood—a son.
HUNT.—On Sept. 24, in London, the wife of Mr. A. H. Hunt, F.R.C —a daughter.
MACWILLIAM.—On Sept. 22, at Burnley, the wife of Dr. J. MacWilliam—a daughter.
MONYPENNY.—On Sept. 24, at Sheffield, to Dr. Isabelle Monypenn (*née* Little), wife of Dr. E. R. Monypenny—a daughter.
NICOLL.—On Sept. 24, in London, the wife of Lieut.-Colonel J. A Vere Nicoll, R.A.M.C.—a daughter.
O'BRIEN.—On Sept. 14, in London, the wife of Dr. D. J. O'Brie —a son.
THOMSON.—On Sept. 23, at Bournemouth, the wife of Dr. R. W Thomson—a daughter.
WOODARD.—On Sept. 23, in London, the wife of Dr. C. R. Woodar —a son.

MARRIAGES

ARMSON—NEWTON.—On Sept. 20, at Hanbury, Gerald Armso M.R.C.S., to Margaret Fenella Newton.
GRAY—GOODCHILD.—On Sept. 20, at East Horndon, Essex, Pet William Spencer Gray, M.B., to Maria Louisa Goodchild.
MICHELL—PEARCE.—On Aug. 30, in London, Guy Michell, M.B to Anne Pearce, S.R.N.

DEATHS

BRIDGE.—On Sept. 27, at Worthing, John Crosthwaite Brid O.B.E., M.R.C.P.E., F.R.C.S.E., D.P.H.
COPLAND.—On Sept. 21, at Leeds, James George Copland, M. M.D. Aberd., aged 65.
EDWARDS.—On Sept. 18, at Fordingbridge, Hants, Walter Goldworthy Edwards, L.R.C.P.E., surgeon captain, R.N. (retd.).
FARMER.—On Sept. 20, at Ludlow, William Henry Farmer, M.R.C. aged 76.
JOSEPH.—On Sept. 8, in Australia, Henry Stanley Joseph, M. Lond., F.R.C.S.
LAPAGE.—On Sept. 23, at Didsbury, Manchester, Charles P. Lapage, M.D. Manc., F.R.C.P.
MILES.—On Sept. 24, in London, William Ernest Miles, T.D., F.R.C. F.R.C.S.I., F.A.C.S.
RITCHIE.—On Sept. 25, in London, Douglas David Ritchie, M. M.D. St. And.
STRATHAIRN.—On Sept. 19, at Nicosia, Cyprus, George Ce Strathairn, M.B. Edin., D.P.H.

but may impair the growth and vitality of the fœtus and also lactation.

The health and physique of the mother depend on the conditions existing at various times from her birth till the birth of her child. Before the war the diet of the high income-group was much superior to that of the poor, and the present investigation has shown that, during the war years, in Aberdeen at least, the high income-group still had a much better diet than the poor. The former had therefore from birth a superior environment leading to better physique and health, and during pregnancy a better diet. One could therefore expect a much better "reproductive performance" from group 1 than group 2. It must also be remembered that the patients in group 1 are much quicker in seeking the best possible medical advice, and more conscientious in carrying out any instructions. How far a first-class diet, backed up by intensive health education, during pregnancy can overcome the handicap of poor health and physique is uncertain.

AGE AND PARITY

We know that the stillbirth-rate rises with age in each parity and that after the second pregnancy it rises with increasing parity. Fig. 1 is an analysis of the births in England and Wales for 1939 and shows that in social class V over half the primiparæ were under the age of 25, whereas in class I the figure was only 17%. This high proportion of young mothers in social class V tends to lower the stillbirth-rate in this group.

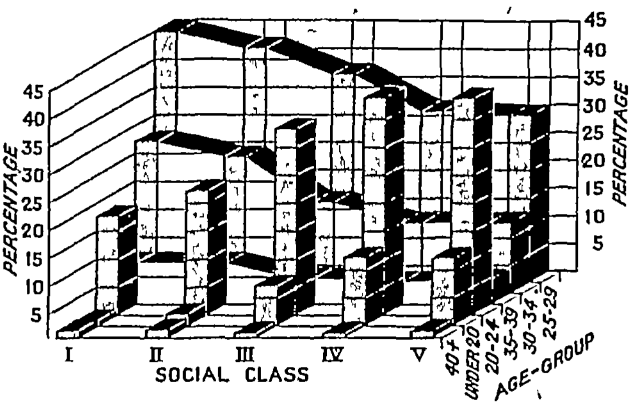

Fig. 1—Analysis of first births in England and Wales in 1939, by social class and age at birth of child.

In social classes I and II the average age at the birth of the first child is about 5 years greater than in social classes III, IV, and V. Families are smaller; so relatively there are more first births. These two factors tend to raise the stillbirth-rate in classes I and II. There are no families of 6 or over, however, in social classes I and II, whereas in classes III, IV, and V large families are still found (6%). In Aberdeen 12% of women in classes III, IV, and V had 6 or more children, with a consequent increase in the stillbirth-rate.

Fig. 2 is an analysis of the stillbirth-rates in primiparæ in the various social classes in England and Wales for 1939: it shows a steady rise with increasing age, starting at 20 years, except in class I, where the rise does not begin until 30. Fig. 3 shows a similar analysis for second pregnancies. Here the difference between social class I and the others is even clearer. In class I the stillbirth-rate rises very little till the age of 40, whereas in class V it rises steadily after 30.

At ages 30-34 the stillbirth-rate in second pregnancies in class V is three times that in class I. The fact that the difference in the stillbirth-rate between classes I and V is greater in a second pregnancy than a first is probably attributable to different factors operating in the two classes. Certain adverse factors in social class V—such as contracted pelvis and poor physique, health, and nutrition—influence the second pregnancy as well as the first, whereas in social class I one of the most important adverse factors in a first labour is difficult labour, due to uterine dysfunction and occipito-posterior positions which does not usually recur in a second labour.

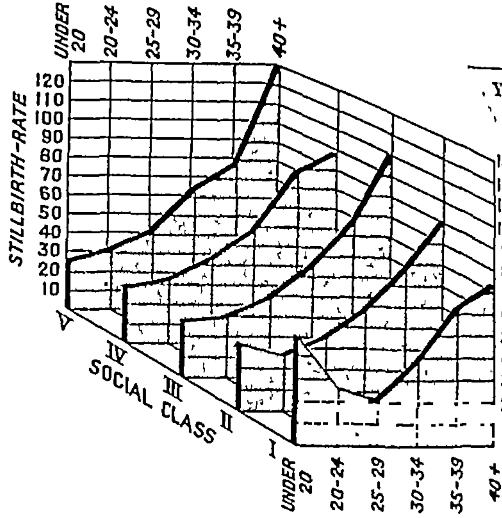

Fig. 2—Stillbirth-rate in primiparæ in England and Wales in [illegible] analysed by age-group and social class.

OBSTETRIC SKILL

To test the influence of skilled care during pregnancy and labour in lowering fœtal mortality, the results obtained by obstetric specialists working in private practice among patients in social classes I and II (group A1), and in hospital practice with patients in social classes III, IV, and V (group B1), have been compared with the results obtained where the standard of obstetric care is average and variable. For this latter group national statistics have been used. Social classes I and II (group A) and social classes III, IV, and V (group B) are obtained by appropriate addition from the data already shown in figs. 2 and 3.

The figures in group A1 are the collected results of six obstetric specialists, and I am much indebted to colleagues in Edinburgh, Glasgow, Leeds, Liverpool, and Belfast for furnishing me with notes of their cases. The total number is small, 2028, but the similarity of the results obtained by each is very striking and suggests that with a larger series the results would be the same. The patients in group B1 were booked cases in the Aberdeen Maternity Hospital.

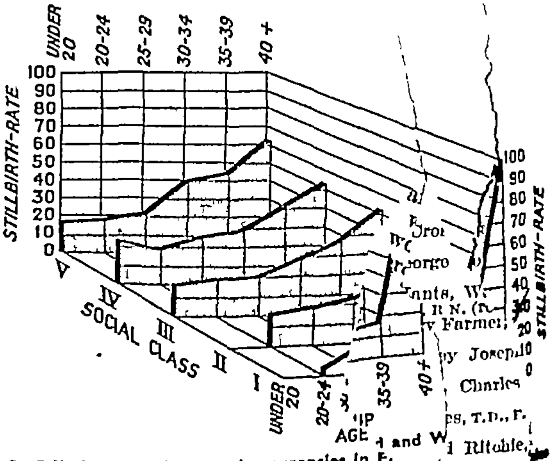

Fig. 3—Stillbirth-rate in second pregnancies in E[illegible] 1939, analysed by age-group and social class.

but may impair the growth and vitality of the fœtus and also lactation.

The health and physique of the mother depend on the conditions existing at various times from her birth till the birth of her child. Before the war the diet of the high income-group was much superior to that of the poor, and the present investigation has shown that, during the war years, in Aberdeen at least, the high income-group still had a much better diet than the poor. The former had therefore from birth a superior environment leading to better physique and health, and during pregnancy a better diet. One could therefore expect a much better "reproductive performance" from group 1 than group 2. It must also be remembered that the patients in group 1 are much quicker in seeking the best possible medical advice, and more conscientious in carrying out any instructions. How far a first-class diet, backed up by intensive health education, during pregnancy can overcome the handicap of poor health and physique is uncertain.

AGE AND PARITY

We know that the stillbirth-rate rises with age in each parity and that after the second pregnancy it rises with increasing parity. Fig. 1 is an analysis of the births in England and Wales for 1939 and shows that in social class v over half the primiparæ were under the age of 25, whereas in class I the figure was only 17%. This high proportion of young mothers in social class v tends to lower the stillbirth-rate in this group.

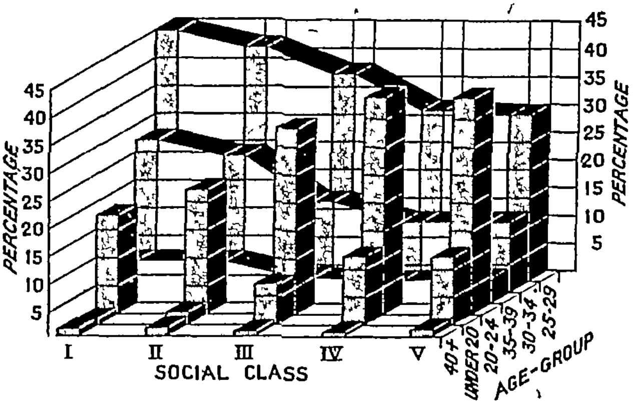

Fig. 1—Analysis of first births in England and Wales in 1939, by social class and age at birth of child.

In social classes I and II the average age at the birth of the first child is about 5 years greater than in social classes III, IV, and v. Families are smaller; so relatively there are more first births. These two factors tend to raise the stillbirth-rate in classes I and II. There are no families of 6 or over, however, in social classes I and II, whereas in classes III, IV, and v large families are still found (6%). In Aberdeen 12% of women in classes III, IV, and v had 6 or more children, with a consequent increase in the stillbirth-rate.

Fig. 2 is an analysis of the stillbirth-rates in primiparæ in the various social classes in England and Wales for 1939: it shows a steady rise with increasing age, starting at 20 years, *except in class I, where the rise does not* begin until 30. Fig. 3 shows a similar analysis for second pregnancies. Here the difference between social class I and the others is even clearer. In class I the stillbirth-rate rises very little till the age of 40, whereas in class v it rises steadily after 30.

At ages 30–34 the stillbirth-rate in second pregnancies in class v is three times that in class I. The fact that the difference in the stillbirth-rate between classes I and v is greater in a second pregnancy than a first is probably attributable to different factors operating in the two classes. Certain adverse factors in social class v—such as contracted pelvis and poor physique, health, and nutrition—influence the second pregnancy as well as th first, whereas in social class I one of the most importa adverse factors in a first labour is difficult labour, du to uterine dysfunction and occipito-posterior position which does not usually recur in a second labour.

OBSTETRIC SKILL

To test the influence of skilled care during preg and labour in lowering fœtal mortality, the re obtained by obstetric specialists working in pri practice among patients in social classes I an (group A1), and in hospital practice with patient social classes III, IV, and V (group B1), have been c pared with the results obtained where the standard obstetric care is average and variable. For this l group national statistics have been used. Social cl and II (group A) and social classes III, IV, and V (grou are obtained by appropriate addition from the already shown in figs. 2 and 3.

The figures in group A1 are the collected results of obstetric specialists, and I am much indebted to leagues in Edinburgh, Glasgow, Leeds, Liverpool, Belfast for furnishing me with notes of their cases. total number is small, 2928, but the similarity of results obtained by each is very striking and sug that with a larger series the results would be the The patients in group B1 were booked cases in Aberdeen Maternity Hospital.

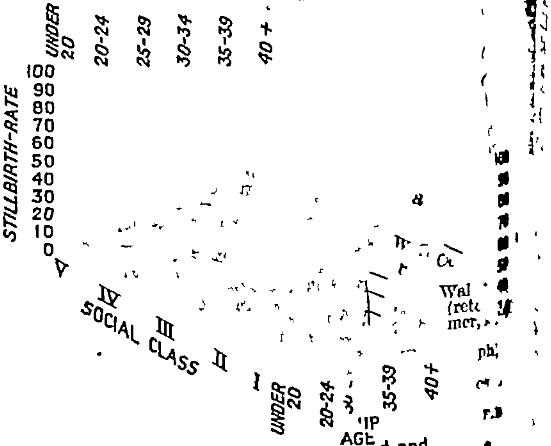

Fig. 3—Stillbirth-rate in second pregnancies in E 1939, analysed by age-group and social class.

relatively high mortality from cerebral birth trauma in full-time infants is a reflection of the higher incidence of contracted pelvis in group B1. The mortality from infection, even in full-time infants, is three times higher in group B1 than in group A1, a result probably of lower resistance to infection and of the greater risk resulting from the higher incidence of difficult labour.

Table VI shows that in group B1 nearly half the neonatal deaths occur in premature infants. These figures agree with national statistics, and though prematurity is not necessarily a cause of death it is a very important predisposing factor. The death-rate per 1000 live births attributed to prematurity in social class V is twice that of social class I, and table V shows that in group B1 there were 54 deaths of premature infants out of 3174 live births (17 per 1000), whereas in group A1 there were 8 deaths in premature infants out of 1605 live births (5 per 1000).

CONCLUSION FROM ABOVE ANALYSES

Evidently the main reason why fœtal mortality is higher in group B1 than in group A1 is the greater incidence of prematurity and of deaths from "unknown" causes. There is a higher death-rate in group B1 from birth trauma, toxæmia, and infection. Since the standard of obstetric care in both groups is high, the contrast must be due to the great differences in physique, health, and diet of the mothers.

TABLE V—CAUSES OF STILLBIRTHS IN FIRST BIRTHS IN TWO GROUPS OF WOMEN UNDER THE CARE OF SPECIALISTS

Group A1 corresponds to social classes I and II, and group B1 corresponds to social classes III, IV, and V

Cause of death	Group B1 (3296 cases)				Group A1 (1633 cases)			
	Full-time	Pre-mature	Total	Still-births per 1000	Full-time	Pre-mature	Total	Still-births per 1000
Gross fœtal deformity	5	11	16	4·9	5	1	6	3·7

Cord complications	1	—	1	0·3	2	—	2	1·2
Accidental hæmorrhage	5	6	11	3·3	—	2	2	1·2
Miscellaneous	2	5	7	2·1	3	—	3	1·8
Total ..	60	62	122	37·0	23	5	28	17·1

"Cause unexplained" in full-time stillbirths refers to those cases where intra-uterine deaths occurred during "normal" pregnancy or labour. In the premature group it means that the cause of the onset of the premature labour was unknown. Under accidental hæmorrhage are included only those where there was no maternal toxæmia.

Group B1 in the present investigation is equivalent to social classes III, IV, and V; and since these classes constitute about 90% of our population the most effective method of lowering the national stillbirth-rate and neonatal mortality would be to raise the living conditions and diet of this 90% to the standard of the other 10%. This would lead to less prematurity and a fall in the numbers of unexplained stillbirths. A long-term effect would be to lower the death-rate from cerebral birth trauma by decreasing the incidence of contracted pelvis.

WAR-TIME EXPERIENCES

Observations in animals have emphasised the importance of a good diet—particularly in the second half of pregnancy—in securing offspring of good vitality and a low stillbirth-rate. Large-scale experiments on the human subject are difficult to carry out, but the experience of Britain during the war years sheds a good deal of light on the influence of diet on stillbirth-rate and neonatal mortality.

TABLE VI—CAUSES OF NEONATAL DEATH IN PRIMIPARÆ GROUPS A1 AND B1

Cause of death	Group B1 (3174 cases)				Group A1 (1605 cases)

In England and Wales, for many years before the war, there was little change in the stillbirth-rate; but between 1939 and 1945 it fell in England and Wales from 38 to 28, and in Scotland from 42 to 33. The improvement affected every age-group and every parity almost equally. A fall in that part of the neonatal mortality ascribed to prematurity and to "congenital debility" also occurred. The Registrar-General for Scotland has analysed the causes of stillbirths for each year from 1939 to 1944, and his analyses for 1939 and 1944 are seen in table VII.

In 1939 the biggest group (32·6% of the total) was called "ill-defined and unknown causes." Deaths due to injury constituted 23·9% of the total. In 1944 the biggest fall in mortality is seen in the "ill-defined and unknown causes" group, which now constitutes 16·6% of the total, and the death-rate from this cause has fallen to nearly a third of what it was. Other causes of stillbirth which have fallen are toxæmia and accidental hæmorrhage; the death-rate from fœtal abnormality has risen. The fall in the number of deaths ascribed to "unknown causes" may be explained to some extent by more accurate certification since 1939, when registration of

TABLE VII—ANALYSIS OF CAUSES OF STILLBIRTH IN SCOTLAND, 1939–44

Cause of stillbirth	1939 (total births 90,731)		1944 (total births 99,162)	
	No. of stillbirths	Still-birth-rate per 1000 (42·2)	No. of stillbirths	Still-birth-rate per 1000 (32·5)
Diseases not specially associated with pregnancy	77 (*2·0%*)	0·84	101 (*3·1%*)	1·01
Diseases specially associated with pregnancy	864 (*22·5%*)	*9·53*	710 (*22·04%*)	7·16
Anomalies of fœtus, placenta, or cord	712 (*18·5%*)	7·84	852 (*26·4%*)	8·59
Death of the fœtus by injury	916 (*23·9%*)	10·09	1017 (*31·5%*)	10·25
Ill-defined and unknown causes	1263 (*32·9%*)	13·92	541 (*16·7%*)	5·45
Total ..	3832		3221	

perienced symptoms of this sort before operation; they d started about six months after it and were now gradually reasing in severity.

As his symptoms suggested hypoglycæmia, a standard T.C. was carried out and gave the following result:

Fasting ..	0·104 g. per 100 c.cm.
$^1/_2$ hr. ..	0·198 g. „ „
1 hr. ..	0·078 g. „ „
2 hr. ..	0·047 g. „ „
$2^1/_2$ hr. ..	0·061 g. „ „

Two hours after drinking the glucose he experienced a pical attack of hypoglycæmia, with sweating, pallor, chycardia, and dilated pupils. These symptoms continued til the end of the test and were then relieved with $^1/_2$ oz. glucose taken by mouth.

He was told to take sugar whenever he felt an attack eloping, and he found that this always relieved his ptoms; but he often forgot his sugar, and the attacks inued to be troublesome.

igations

e following investigations were carried out on this man outpatient. Throughout the tests he took a full normal except where the contrary is stated, and whenever he to hospital he rested on a bed in the ward for an hour fore any test was started.

A second G.T.C. gave the following result:

Fasting ..	0·077 g. per 100 c.cm.
$^1/_2$ hr. ..	0·213 g. „ „
1 hr. ..	0·116 g. „ „
$1^1/_2$ hr. ..	0·052 g. „ „
$1^3/_4$ hr. ..	0·065 g. „ „
2 hr. ..	0·077 g. with 1 % glycosuria at $1^1/_2$ hr.

Oral galactose-tolerance curve (40 g. galactose) (fig. 1):

Fasting ..	Nil
$^1/_4$ hr. ..	0·059 g. per 100 c.cm.
$^1/_2$ hr. ..	0·084 g. „ „
$^3/_4$ hr. ..	0·035 g. „ „
1 hr. ..	Nil

naline-sensitivity rve (see fig. 2, Strandell 1934): naline 1 mg. was en intramuscularly to the fasting patient, d blood-sugar was imated at 10-min. ervals. The results per 100 c.cm.) were: ting 0·092; 0·140; 162; 0·170; 0·185; 145.

Insulin-sensitivity test e fig. 3, and Fraser al. 1941): soluble ulin 3 units, equivalent to 0·05 unit per kg. body-weight, was ected intravenously to the fasting patient, d blood-sugar was timated at 4-min. ervals. The results re:

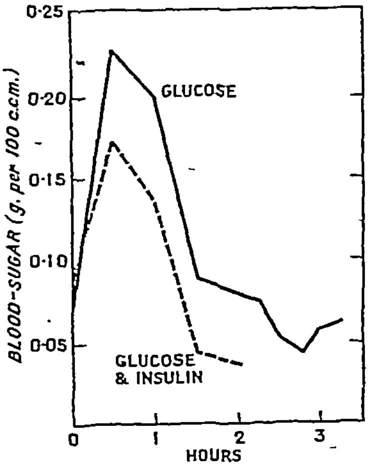

Fig. 4—Glucose-tolerance and insulin-glucose-tolerance curves in case 2.

Fasting	0·073 g. per 100 c.cm.
4 min. after insulin ..	0·080 g. „ „
8 „ „ „ ..	0·056 g. „ „
12 „ „ „ ..	0·061 g. „ „
16 „ „ „ ..	0·040 g. „ „
20 „ „ „ ..	0·033 g. „ „
24 „ „ „ ..	0·042 g. „ „

Symptoms of hypoglycæmia were present 20 min. after the ection.

Radioscopy showed that the patient's stomach emptied com- tely 15 min. after the ingestion of $^1/_2$ pint of barium meal.

The patient was put on a relatively high-fat diet composed about 250 g. of carbohydrate, 165 g. of fat, and 95 g. protein, and this he took readily. His symptoms gradually proved, but war work took him from the district and he is not seen again until Jan. 6, 1944, when the G.T.C. showed eat improvement:

Fasting ..	0·081 g. per 100 c.cm.
$^1/_2$ hr. ..	0·194 g. „ „
1 hr. ..	0·101 g. „ „
$1^1/_2$ hr. ..	0·067 g. „ „
2 hr. ..	0·070 g. „ „
$2^1/_2$ hr. ..	0·075 g. „ „

In December, 1944, while still on this diet, he reported that his attacks had practically ceased, and on June 21, 1945, another G.T.C. showed:

Fasting ..	0·081 g. per 100 c.cm.
1 hr. ..	0·123 g. „ „
2 hr. ..	0·079 g. „ „
$2^1/_2$ hr. ..	0·089 g. „ „

In February, 1946, he returned to normal diet, but a further test on April 17, 1946, showed:

Fasting ..	0·064 g. per 100 c.cm.
$^1/_2$ hr. ..	0·235 g. „ „
1 hr. ..	0·186 g. „ „
$1^1/_2$ hr. ..	0·066 g. „ „
2 hr. ..	0·056 g. „ „

with glycosuria at half an hour, and he was again experiencing slight symptoms. He therefore returned to his high-fat diet and has continued well ever since.

While he was on this diet, the insulin-sensitivity test was repeated on May 7, 1946, and gave the following result (fig. 3):

Fasting	0·092 g. per 100 c.cm.
4 min. after insulin ..	0·105 g. „ „
8 „ „ „ ..	0·075 g. „ „
12 „ „ „ ..	0·078 g. „ „
16 „ „ „ ..	0·054 g. „ „
20 „ „ „ ..	0·054 g. „ „
24 „ „ „ ..	0·060 g. „ „

Case 2.—A labourer, aged 42, had had recurrent exacerbations of a prepyloric ulcer since 1938. He was admitted to Hillingdon Hospital in May, 1943, with a further recrudescence; and, because of his lack of response to medical treatment, and his high gastric acidity, operation was advised.

Partial gastrectomy (Polya) was done by Mr. Gordon Duncan on May 27, 1943; convalescence was uneventful.

Patient reported to the follow-up clinic in August, 1943, complaining of such severe bouts of physical exhaustion and vertigo two or three hours after his meals that he could not stand up. These attacks were accompanied by trembling, emotional instability, and paræsthesiæ of the feet. Sweating was not mentioned spontaneously, but was admitted on direct questioning. He had noted that these symptoms were particularly likely to come on if he took exercise after a meal.

A standard G.T.C. on Aug. 25, 1943, gave the following figures:

Fasting ..	0·100 g. per 100 c.cm.
$^1/_2$ hr. ..	0·260 g. „ „
1 hr. ..	0·120 g. „ „
2 hr. ..	0·047 g. „ „
3 hr. ..	0·065 g. „ „

There was glycosuria in the half-hour specimen, and patient was shaky and uneasy two hours after the test began.

Investigations

Patient was admitted to hospital, and the following investigations were carried out while he was on the full ward diet.

Glucose-tolerance curve, Oct. 21, 1943 (52 g. of glucose, equivalent to 30 g. per sq. m. of body surface; see fig. 4):

Fasting ..	0·074 g. per 100 c.cm.
$^1/_2$ hr. ..	0·228 g. „ „
1 hr. ..	0·198 g. „ „
$1^1/_2$ hr. ..	0·089 g. „ „
2 hr. ..	0·080 g. „ „
$2^1/_4$ hr. ..	0·074 g. „ „
$2^1/_2$ hr. ..	0·052 g. „ „
$2^3/_4$ hr. ..	0·044 g. „ „
3 hr. ..	0·075 g. „ „

There was glycosuria at 1 hr. and symptoms of hypoglycæmia at $2^1/_2$ hr.

Insulin-glucose curve, Oct. 23, 1943 (see fig. 4 and Himsworth 1939b): while patient drank 52 g. of glucose, soluble insulin 5 units was injected intravenously. Had Himsworth's technique been exactly followed, $8^1/_2$ units would have been injected, but it was felt that this dose might cause excessive hypoglycæmia in this patient. The following results were obtained:

Fasting ..	0·089 g. per 100 c.cm.
$^1/_2$ hr. ..	0·173 g. „ „
1 hr. ..	0·136 g. „ „
$1^1/_2$ hr. ..	0·043 g. „ „
2 hr. ..	0·037 g. „ „

At 2 hr. hypoglycæmia was so severe that the test was stopped.

Adrenaline-sensitivity curve (see fig. 2 and Strandell 1934): 1 mg. of adrenaline was injected intramuscularly into the fasting patient, and the blood-sugar estimated at 10-min. intervals, with the following results (g. per 100 c.cm.): fasting 0·061; 0·103; 0·118; 0·132; 0·141; 0·127; 0·132.

HYPOGLYCÆMIA FOLLOWING PARTIAL GASTRECTOMY

REPORT OF THREE CASES

CYRIL G. BARNES
M.D. Lond., F.R.C.P.
PHYSICIAN, HILLINGDON COUNTY HOSPITAL, MIDDLESEX

AFTER patients have undergone partial gastrectomy for peptic ulcer their blood-sugar level may fluctuate remarkably for some months. Sometimes the blood-sugar abruptly increases after a meal so much that the renal threshold is far exceeded and glycosuria results; and then, within an hour or two, it decreases so rapidly or to so low a level that symptoms of hypoglycæmia develop.

Such attacks of hypoglycæmia have aroused little interest in this country, and most of them probably pass undiagnosed. There are, however, several German references to this subject, and Evensen (1942) has published his detailed work on alimentary hypoglycæmia and reviewed the literature. Three cases are reported here in which hypoglycæmia of great severity followed partial gastrectomy for peptic ulcer.

In the standard glucose-tolerance curve (G.T.C.) three distinct phases can be recognised: (1) increasing glycæmia during which the rate of absorption of glucose exceeds that of its storage in the liver and muscles, the blood-sugar level reaching a peak 30–60 min. after ingestion of the glucose; (2) decreasing glycæmia, when the storage of sugar under the influence of insulin outpaces its absorption, the blood-sugar level returning to the fasting level, *or somewhat lower*, 90–120 min. after the start of the test; and (3) the blood-sugar increases again slowly to the fasting level, as glucose is liberated from the liver by adrenaline secreted in response to the falling blood-sugar level of the second stage. Even in a few normal persons the blood-sugar level falls so sharply during the second phase of the curve that mild symptoms of hypoglycæmia are produced; Evensen recorded such symptoms in 3 of his 50 normal subjects during a standard G.T.C.

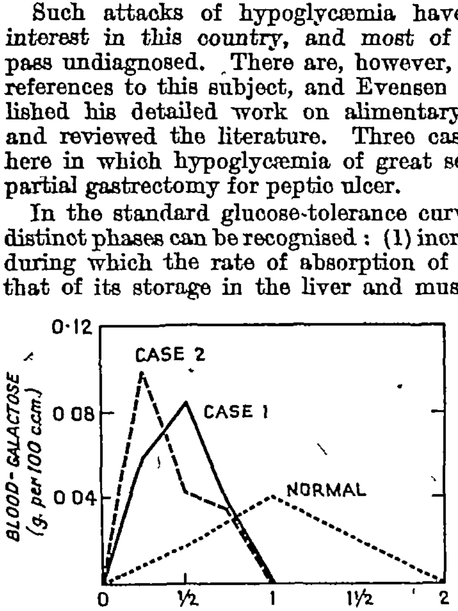

Fig. 1—Oral galactose-tolerance tests in cases 1 and 2.

Maclean (1932) first drew attention to an unusual type of G.T.C., which he named the "lag curve." In this the first stage is abnormally abrupt, the blood-sugar level reaching a peak above the renal threshold within 30 min., causing transient glycosuria. An unusually rapid fall of blood-sugar level marks the second phase, often bringing the blood-sugar 0·030 g. or more per 100 c.cm. below the fasting level an hour after the start of the test. It was pointed out by Lawrence (1936) that such curves were common in patients who had undergone gastro-enterostomy or had duodenal ulcer, and he associated curves of this shape with rapid emptying of the stomach, preferring the name "oxyhyperglycæmic" curve to that of lag curve. The fact that similar curves have been recorded in normal people when the glucose is introduced through a tube directly into the duodenum (Wöhrle 1936, Evensen 1942) is in accordance with this view, but it is important to note that Evensen's figures show clearly that the hypoglycæmic phase is not well marked in such experiments, and to this point Wöhrle drew particular attention. Evensen demonstrated that in 7 out of 50 patients with peptic ulcer, and 17 out 37 cases of gastro-enterostomy, the blood-sugar rose to a peak of 0·210 g. per 100 c.cm. or higher d a standard G.T.C. and fell to 0·065 g. per 100 c.cm. or lower during the second phase. Mild symptoms of hypoglycæmia developed during the test in 4 of the patients with ulcer and 14 of those with gastro-enterostomy. It is not common for symptoms to develop *in such patients after a normal meal*, for glucose is then absorbed more slowly and for a longer time as the polysaccharides of the meal are gradually digested.

After certain types of partial gastrectomy for peptic ulcer the stomach empties with great rapidity and an oxyhyperglycæmic type of G.T.C. is found. Even after ordinary meals slight glycosuria develops, and this may be followed from one to three hours later by symptoms of hypoglycæmia. These symptoms are particularly apt to develop if hard physical work is being done while the blood-sugar level is falling, and it is well recognised that physical exertion may produce a considerable fall in blood-sugar level even in normal people (Strandell 1934). It is a remarkable feature of these *cases that symptoms of hypoglycæmia start not immediately* after the operation but only after a lapse of weeks or months; any theory to explain the mechanism of these hypoglycæmic attacks must take this fact into account. Evensen (1942) found mild symptoms of hypoglycæmia during a G.T.C. with a blood-sugar level of 0·065 g. per 100 c.cm. or less in 12 of his 95 cases of partial gastrectomy.

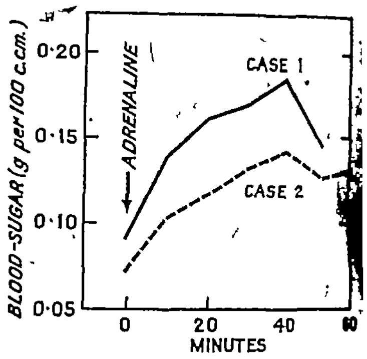

Fig. 2—Adrenaline-sensitivity curves in cases 1 and 2.

The following case-records show that events in these patients follow a characteristic course, with the result that diagnosis is not difficult, and that on occasion the symptoms may be so severe that the patient is incapacitated.

Case 1.—A male clerk, aged 28, had had a severe hæmatemesis *in 1936 and since that time had experienced* several attacks of epigastric pain.

He was admitted to Hillingdon Hospital *on Sept. 30*, 1941, with another hæmatemesis, from which he recovered. Radiography then showed a duodenal ulcer with early stenosis, and a test-meal revealed great hyperchlorhydria.

Partial gastrectomy (Polya) was done by Mr. Gordon Duncan on Nov. 6, 1941, and recovery was uneventful, patient being discharged on Dec. 13, 1941.

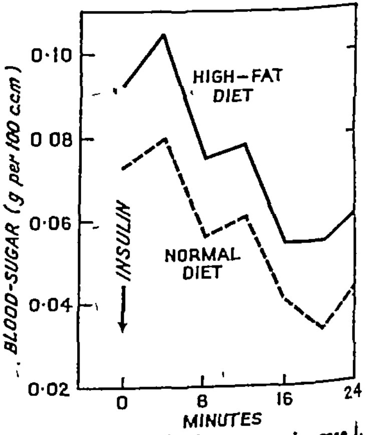

Fig. 3—Insulin-sensitivity curves in case I.

On May 18, 1943, he attended the follow-up clinic, complaining of attacks of intense exhaustion and muscular weakness, accompanied by mental irritability and a feeling of great anxiety. At such times his hands trembled violently and he sweated profusely. Attacks came on two or three hours after food, and seemed to him to be precipitated by physical exertion, such as digging in his garden. He had never

Galactose-tolerance curve (40 g. galactose by mouth, see fig. 1):

Fasting	..	Nil
¼ hr.	..	0·098 g. per 100 c.cm.
½ hr.	..	0·041 g. ,, ,,
¾ hr.	..	0·036 g. ,, ,,
1 hr.	..	Nil

Emptying-rate of stomach.—After a half-pint barium meal, radioscopy showed that the stomach had emptied completely within 15 min.

Patient was discharged and seen regularly in the out-*patient department. He refused to take a high-fat diet, and* his attacks continued, being relieved by sugar and bread. A G.T.C. on Dec. 5, 1944, showed:

Fasting	..	0·061 g. per 100 c.cm.
1 hr.	..	0·130 g. ,, ,,
2 hr.	..	0·043 g. ,, ,,
2¼ hr.	..	0·044 g. ,, ,,
2½ hr.	..	0·040 g. ,, ,,
2¾ hr.	..	0·045 g. ,, ,,

Gradually his symptoms became less and less troublesome, and when the patient was last seen in June, 1946, he reported that they had practically ceased.

Case 3.—A male, aged 46, had undergone partial gastrectomy (Polya) in December, 1942, for duodenal ulcer. In April, 1944, he began to complain of headaches, giddiness, lack of concentration, and "feeling blank," usually about 4 P.M. These symptoms became disabling and their indefinite nature led his doctor to send him to a psychiatrist, but he was subsequently transferred to Dr. M. M. Deane at the West Middlesex Hospital, who diagnosed hypoglycæmia.

A G.T.C. then showed:

Fasting	..	0·100 g. per 100 c.cm.
½ hr.	..	0·240 g. ,, ,,
1½ hr.	..	0·044 g. ,, ,,
2 hr.	..	0·044 g. ,, ,,
3 hr.	..	0·090 g. ,, ,,

A half-pint barium meal was given, and the radiologist reported: "The stomach empties very rapidly and retains barium meal for no more than 5 or 6 minutes. The stoma is apparently dilated."

The symptoms *improved spontaneously, and a G.T.C. in* January, 1945, showed:

Fasting	..	0·104 g. per 100 c.cm.
½ hr.	..	0·170 g. ,, ,,
1 hr.	..	0·142 g. ,, ,,
1½ hr.	..	0·110 g. ,, ,,
2 hr.	..	0·090 g. ,, ,,
2½ hr.	..	0·092 g. ,, ,,
3 hr.	..	0·078 g. ,, ,,
3½ hr.	..	0·088 g. ,, ,,

Since then patient has been free from symptoms.

NOTE ON OPERATIVE TECHNIQUE IN CASES 1 AND 2

(G. W. Duncan, M.B. Lond., F.R.C.S.E.)

Case 1 had a large duodenal ulcer fixed to the pancreas. The stomach was divided proximal to the pylorus, and the mucosa of the pyloric antrum was removed after the method of Finsterer. Three-quarters of the stomach was removed, and a retrocolic Polya anastomosis was performed, the whole length of the cut stomach being used for the anastomosis. The stoma was 4 in. long.

In case 2 a chronic duodenal ulcer was found. Resection comprised over three-quarters of the stomach and the first part of the duodenum, including the ulcer. A retrocolic Polya anastomosis was performed, utilising the whole length of the cut stomach as in case 1.

In each case a large stoma was made, and both these patients had a retrocolic anastomosis. Since a modified *Hofmeister type of anastomosis, with a much smaller stoma,* has been used, no case exhibiting symptoms of hyperglycæmia after operation has been found in over 100 cases.

Methods.—In cases 1 and 2 blood-glucose was estimated titrimetrically on capillary blood by Harding's modification of the Schaffer-Hartmann technique (see King 1946a). Blood-galactose was estimated by the method described by King (1946b) on capillary blood.

DISCUSSION

A characteristic clinical picture emerges from these case-records identical with that described by Evensen (1942). A patient undergoes partial gastrectomy by a technique which leaves a large stoma through which stomach empties with great rapidity. He keeps well some weeks or months after leaving hospital, and begins to develop, about two hours after his particularly if he is doing manual work then, mu weakness, sweating, trembling, palpitations, and tional instability. These symptoms may be p by glycosuria, are accompanied by pallor, tachyc and dilated pupils, and are quickly relieved by f *In mild cases the patient may be thought* psychone and the true diagnosis not considered, but in severe c the picture is unmistakable. The diagnosis is confir by a G.T.C., which shows an oxyhyperglycæmic c with a sharp drop of blood-sugar level to hypogly levels two or three hours after the start of the test, w the patient may declare that one of his attacks is dev ing. Symptoms depend as much on the rate of the blood-sugar level as on its ultimate level. sugar estimations should be made every quarter hour for two and a half or three hours, otherwise lowest point in the curve may be missed.

There can be no doubt that these three patients attacks of hypoglycæmia, for their symptoms w identical with those of hypoglycæmia from other ca they were relieved within a few minutes by ingestion glucose, and in the G.T.C. they coincided with a rap *decrease of blood-sugar from a high level to a* value 0·050 g. per 100 c.cm. or less. None of them had experienced such symptoms before operation.

The results of investigations carried out on cases 1 a suggest a mechanism by which the abnormal curves hypoglycæmia are brought about. In each case first phase of the G.T.C. is abnormal, the blood-sugar rising steeply to a higher value than normal, prod glycosuria. This is probably due to such rapid absorp *of sugar that hyperglycæmic levels are reached* be the storage action of insulin becomes effective. confirmation, radioscopy shows that the stomach emp very quickly through the large stoma of the Polya op tion. It is possible, however, that the hyperglycæ might result from the patient's inability to store absorbed glucose as glycogen in the liver or muscles, eit from some disease of the liver or from some failure in production of insulin, the operation having interf with the blood-supply or nervous connexions of pancreas. But there has been no clinical evidence of hepatic disorder in either patient in the three years du which they have been under observation, and the rap removal of the galactose from the blood-stream in galactose-tolerance tests argues strongly against disease of the liver. The high peaks in both the galacto curve and the glucose-tolerance curve show clear that the hyperglycæmia cannot be due to deficie production of insulin, for the metabolism of galacto is independent of insulin action (Roe and Schwartzma 1932). The close similarity between the two curv also demonstrates that the hyperglycæmia cannot caused by excessive hepatic glycogenolysis dur absorption, as was maintained by Hetényi and Pog (1928), for galactose is not re-formed from liver glycog (Harding et al. 1934). The first phase of the blood sugar curves in these patients is therefore adequat explained on the grounds of unusually rapid absorpti of sugar from the intestine.

Three mechanisms might explain the sharp fall blood-sugar level during the second stage of the curv In the first place, the body might react to the high blood sugar level of the first stage by the secretion of unusually large amount of insulin, the maximal e of which might coincide with the completion of gluc absorption and so lead to hypoglycæmia. Such mechanism is not easy to confirm or disprove, for the is no means of determining the amount of insulin blood or tissues at any moment.

ain β-halogenated alkylamines. Their profound ressant effect on leucopoiesis occurred much earlier n any effects on the red-cell series, and it was usually owed by a rapid improvement if the patient was pletely and promptly removed from exposure to these e agents. This led to a consideration of the possible apeutic effects of these substances. For this purpose, following two substances were chosen for trial as t of our experience on the large scale had been with n: methyl-bis(β-chlorethyl)amine hydrochloride and (β-chlorethyl)amine hydrochloride.

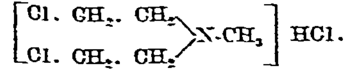
n the first place these substances were tried in 1942 patients with chronic lymphatic and chronic myeloid emia, who were specially selected as having very high al white-cell counts, so that a considerable depression he leucocytes could be observed without risk. With erience we extended our investigations to all types and rees of acute and chronic leukæmia, polycythæmia, Hodgkin's disease. The whole of the original work done during the war, when the substances used were ject to severe restrictions of secrecy, and it is only r that we can report briefly our results with these nal cases and some additional ones. Meanwhile ilar investigations have been reported from America several groups of workers (Gilman and Philips 1946, lman et al. 1946, Jacobson et al. 1946, Rhoads 1946) n these agents in leukæmia, Hodgkin's disease, and phosarcoma.

rom the small series of cases described in this report do not attempt to assess the ultimate prognosis in e cases but are primarily concerned with observa- on the immediate effects of therapy, though several the investigations have been carried on for several rs. The exact mechanism of the action of these stances remains to be discovered.

DOSAGES AND TECHNIQUE

he two amines were used in the form of their hydro-rides and have been variously termed nitrogen tards, halogenated alkylamines, &c.:

) Methyl-bis(β-chlorethyl)amine hydrochloride

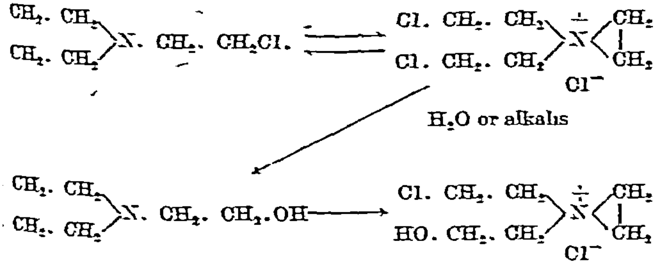


$$\left[\begin{matrix}\mathrm{Cl.\,CH_2.\,CH_2}\\ \mathrm{Cl.\,CH_2.\,CH_2}\end{matrix}\!>\mathrm{N\cdot CH_3}\right]\mathrm{HCl.}$$

) Tris(β-chlorethyl)amine hydrochloride

$$[(\mathrm{Cl.\,CH_2.\,CH_2})_3 \equiv \mathrm{N}]\ \mathrm{HCl.}$$

oth hydrochlorides are easily soluble in water, in ch they tend rapidly to undergo a reversible chemical rangement with the formation, first, of very reactive e ethylene-imonium derivatives, and finally, especi- in the presence of weak alkalis, of relatively inactive ohydrins and the chlorine-free hydroxyamines:



and so on.

as obviously important that these solutions should made up freshly immediately before clinical use.

hese ethylene-imonium derivatives have very potent iotoxic and cytotoxic effects, especially on mitosis the more rapidly proliferating cells and in enzyme tems; consequently the hæmopoietic and gastro-estinal systems are specially affected, even by sub-lethal doses. On standing in water or in the presence of dilute alkali, further hydrolysis forms the chlorohydrin and then complete removal of all the chlorine atoms, and dimerisation may also take place, these substances having little leucopenic activity.

Owing to their highly vesicant properties these two substances were given intravenously in dilute solution, care being taken to prevent leakage into the subcutaneous tissues; we have no record of having any trouble in this connexion. Of the two substances, there was a greater tendency on the part of the bis compound to cause local thrombosis at the site of the injection, but there was very little tendency on the part of the tris compound to do this in the doses we used.

The calculated required doses of these salts were weighed accurately in sterile dry tubes and then dissolved in 30 ml. of sterile isotonic saline and administered intravenously immediately to reduce to the minimum any tendency to hydrolysis.

The usual initial doses were about 0·1–0·2 mg. per kg. of body-weight, administered on consecutive or alternate days until about 3–6 doses had been given; but these were varied according to the blood-count, particularly the number of leucocytes, and to the responses to the previous doses. These results were controlled by daily total white-cell counts and bi-weekly full blood-counts. Various other hæmatological and biochemical examinations not described here were also done. From observations of the effects of the initial doses we were able to adjust subsequent doses to appropriate levels until the required hæmatological effects were produced.

The patients were usually admitted to hospital for the first series of injections, but later injections have been

RESULTS IN CHRONIC MYELOID LEUKÆMIA

Case no.	Age (yr.)	Sex	Duration of disease before treatment (months)	Courses of treatment*	Total dose of alkylamine (mg.)	White cells (thousand)		Comments
						Before treatment	After treatment	
1	37	M	4–6	23	267·0	490	123	Definite improvement with remission of 8 months; anæmia improved with decrease of spleen; refractory stage reached after 14 months
2	63	F	2	3	26·6	210	122	Poor response; no improvement in anæmia
3	60	F	24	8	45·6	87	6	Temporary remission for 2 months; subjective improvement with correction of anæmia and decrease of spleen
4	43	F	6–8	5	127·7	378	159	Remission of 4 months, but not maintained; anæmia and splenomegaly returned and refractory stage reached after 6 months
5	56	F	20	2	18·0	236	49	Moderate improvement maintained
6	40	M	24	6	36·0	391	60	Well-marked improvement with decrease in gross enlargement of spleen; anæmia controlled
7	39	M	6–9	3	24·0	297	89	Well-marked improvement; remission of 4 months continues
8	52	M	6	3	30·0	810	59	Well-marked improvement

*A course usually consisted of 3–6 injections, each of 0·1–0·2 mg. per kg. of body-weight.

TUBERCULOUS RHEUMATISM

REPORT OF A CASE

R. J. T. WOODLAND
M.B. Camb.
LATE SURGEON LIEUTENANT, R.N.V.R.

IN view of the apparent rarity of tuberculous rheumatism,[1] the following case, which presented some unusual features, is worthy of record.

A trainee for the Royal Navy, aged 16, with no relevant personal or family medical history, had been taken ill with sore throat in November, 1944. Tonsillitis had been diagnosed and the boy put to bed.

Progress had been satisfactory for four days, but he had then developed pleuritic pain to the right of the mid-sternum. This had increased rapidly in severity and had been accompanied by a dry cough and a feeling of extreme illness. A mild sore throat had persisted.

A full course of sulphathiazole had been given without apparent effect, and anorexia and toxæmia had begun to cause wasting.

Nov. 28, 1944 (on admission to sick quarters): temperature swinging to 102°F each evening, pulse-rate 110, respirations 23 per min., weight 125 lb.

The patient was pale, thin, and ill-looking, but lay comfortably in bed. He complained of pain in right chest on swallowing, movement, deep respiration, and coughing. Slight sore throat. Thick yellow sputum. Throat injected, but tonsils contained no obvious pus. Tonsillar glands palpable and a little tender. No other glands enlarged. No clubbing. Trachea central. Only abnormality detected in chest was some diminution in movement on right side. D'Espine's sign negative. Heart normal apart from tachycardia. Blood-pressure 120/70 mm. Hg. Abdomen normal. Spleen not palpable. Central nervous system normal. Hb 74%, leucocytes 7600 per c.mm. (neutrophils 64%, lymphocytes 35%, monocytes 2%).

Nov. 30: moderate quantity of bloodstained sputum, containing fibrous plugs.

Dec. 1: pain now more across front of chest and of an aching character. Radiography showed: right chest flattened; right hilar shadows suggesting enlarged mediastinal glands; in the right upper lung field, above the horizontal sulcus, reticulations producing a triangular opacity with the apex toward the mediastinum.

Dec. 11: gradual improvement; pain absent except on swallowing; temperature settled; pulse-rate 90, respirations 20 per min.; erythrocyte-sedimentation rate (E.S.R.) 73 mm. in first hour. Six daily specimens of sputum negative for tubercle bacilli.

Jan. 8, 1945: patient looked and felt much better. Weight 133 lb. Hb 90%; E.S.R. 33 mm. in first hour. Six further specimens of sputum negative for tubercle bacilli.

Radiography showed some diminution in density of opacity in right upper lung field; otherwise no change.

Jan. 21: some return of pain in right anterior chest. Slight coryza, but no sore throat. Tonsils and tonsillar glands in statu quo. E.S.R. 70 mm. in first hour. Radiography of chest showed no appreciable change.

Feb. 2: patient obviously ill again; pale and sweating. Temperature swinging to 101°F in the evening. Pulse-rate 115 per min. Moderately severe pain in both shoulder-joints. No other joints affected. Also severe continuous retrosternal pain, apart from the original pain.

Apex-beat $1^1/_2$ in. outside midclavicular line. Cardiac rhythm tic-tac. Pericardial friction sound clearly audible over lower sternum. Blood-pressure 100/60 mm. Hg. Leucocytes 5500 per c.mm.

Feb. 3: patient still very ill, retrosternal pain persisted, and pleuritic pain in right lower chest appeared. Loud pericardial friction sound continued, and pleural friction sound now heard in right lower anterior axilla. Blood-pressure 95/60 mm. Hg.

Feb. 9: definite improvement; heart sounds more normal; no friction sounds; apex-beat still at least 1 in. out. Radiography showed transverse diameter of heart much increased, suggesting dilatation.

Feb. 14: improvement continued. Pain in shoulders gone (not treated with salicylates). Mantoux 1 : 10,000 positive.

Feb. 20: apex-beat in normal position; cardiac r normal; cardiac shadow normal on radiography.

Feb. 25: patient had had rheumatic pains in neck several days.

March 29: had made gradual steady progress; loo and felt very well; E.S.R. 7 mm. in the first hour; weig 139 lb.

April 16: tonsillectomy performed as a prophylac measure, since it seemed conceivable that the whole illne might be due to streptococcal acute rheumatism and might n be tuberculous. Microscopy of tonsillar sections show tuberculous infiltration.

May 9: recurrence of pain in right anterior chest; so diminution of air entry at right base posteriorly.

May 29: the patient was acutely ill, with pleuritic pain right middle and lower zones posteriorly. Dullness, dimini air entry, and numerous râles at right base. Radiograph appearances suggested a right pleural effusion and area consolidation in right lower zone. On aspiration of right a clear straw-coloured fluid was withdrawn. Leucocyte- (peripheral blood): 6700 per c.mm.

After his transfer to another hospital the pati subsequent progress was satisfactory.

DISCUSSION

Despite the initial acute sore throat, it seems unlik that this case was one of streptococcal rheumatis The long delay in the onset of the allergic manifestatio and the presence of pericarditis and myocarditis witho accompanying endocarditis, suggest that it was a ca of allergy to the tubercle bacillus.

If the tonsillar condition was primary, it see probable that bacilli were inhaled into the right upp lobe, causing partial infiltration of this lobe and sub quent enlargement of hilar glands. This was follow by *the various somewhat unusual allergic manifestatio*

Of possible significance is the contrast between t initial pleurisy, presumably allergic, without effusio and the final pleurisy, presumably due to invasion b bacilli, with effusion.

I am indebted to the Medical Director-General of the Nav and to Surgeon Captain J. H. Burdett, R.N., for hi permission to publish this case.

EFFECT OF β-CHLORETHYLAMINE HYDROCHLORIDES

IN LEUKÆMIA, HODGKIN'S DISEASE, AND POLYCYTHÆMIA VERA

REPORT ON EIGHTEEN CASES

JOHN F. WILKINSON
M.D., Ph.D. Manc., F.R.C.P., F.R.I.C.
PHYSICIAN IN CHARGE AND DIRECTOR

FRANK FLETCHER
M.D. Vict.
SYBIL MARY PILKINGTON RESEARCH FELLOW

Department of Clinical Investigations and Research, University and Royal Infirmary, Manchester

SINCE the 1914–18 war a good deal of knowledge ha been acquired in relation to the general systemic and hæmatological effects of chemical-warfare agents, partic larly the vesicants, such as ββ-dichlordiethylsulphide and similar substances. The main effects on the hæmo poietic system in man and animals have been primarily on the leucocytes, causing neutropenia and agranulo cytosis, with sometimes the later development of aplastic anæmia, thrombocytopenic purpura, or hæmolyti anæmia; early signs may be an inversion of the poly morph-lymphocyte ratio, an unusual eosinophilia, o more rarely a slight basophilia (greater than 1·5%) and often Türk or plasma cells may be seen in the peri pheral blood. These features are almost identical with those produced by X rays.

During the late war, particularly from 1942 onwards the interest of one of us (J. F. W.) led to the observati of almost identical results in man after exposure

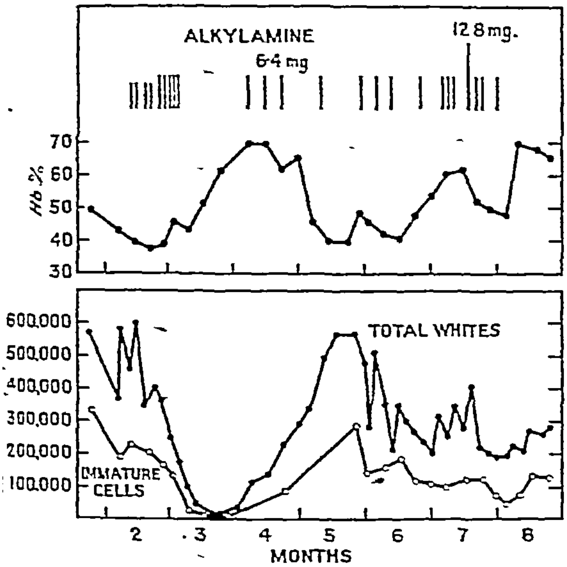

Fig. 3—Chronic myeloid leukæmia (case 4).

ere occasional short remissions of six to fourteen eeks.

odgkin's Disease

In a group of 4 patients with Hodgkin's disease, eated in a similar manner to the leukæmic patients, ere was a striking reduction in the sizes of enlarged mph-nodes, liver, and spleen, with a disappearance f pyrexia (in 1 case within a week of the start of erapy).

In 1 case there was a rapid deterioration in spite of this eatment, and 3 have remained in satisfactory remission p to seventeen weeks without further treatment. The tient who responded poorly was in the terminal stage the disease when admitted to hospital. The 3 other tients experienced dramatic improvement in appetite d weight, with an increased feeling of well-being and ility to exert themselves without undue lassitude. one of these patients had previously had X-ray or her therapy.

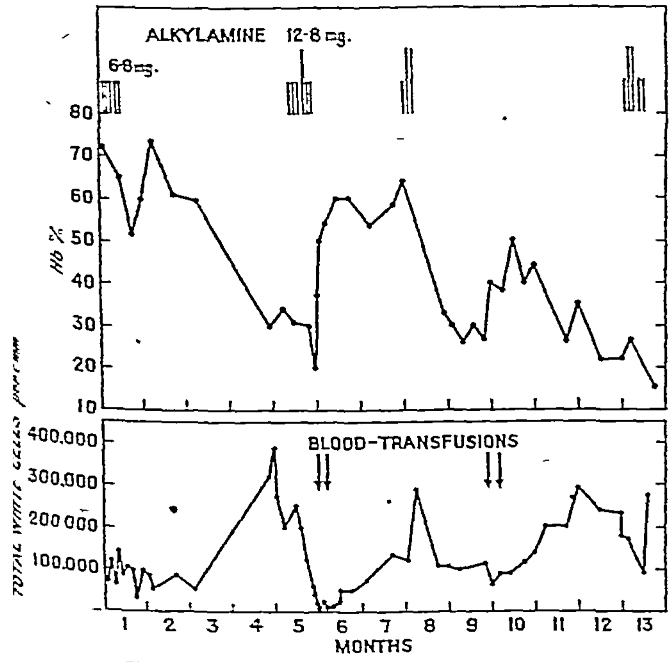

Fig. 4—Chronic lymphatic leukæmia (case 9).

Clinical photographs of 1 case are shown to demonstrate the decrease in the cervical, mediastinal, and hilar lymph-node masses after treatment (figs. 6 and 7).

Polycythæmia Vera

Of 3 cases of polycythæmia treated, only 1 showed any significant subjective and objective improvement with a fall in the total red-cell count and Hb percentage to normal levels. This remission was associated with a complete disappearance of headache, vertigo, and lassitude for nine weeks. In the 2 cases which did not show a satisfactory hæmatological remission there was some tendency for the symptoms to improve transiently. Splenomegaly, present in all cases, was not significantly affected up to two months after the start of treatment.

The blood-counts of the case which responded to treatment are shown graphically in fig. 8, which shows an early depression of the total white-cell count, with a more delayed but increasing fall in the total red-cell count and Hb percentage.

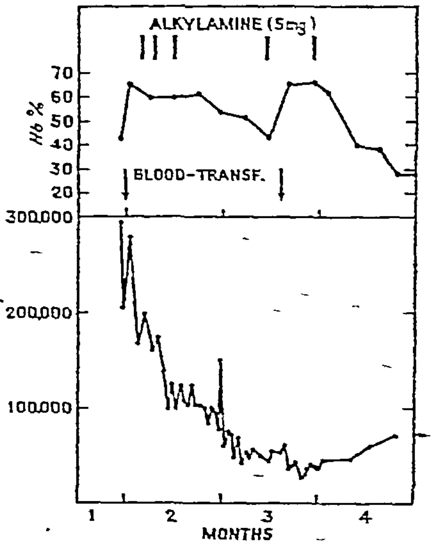

Fig. 5—Chronic lymphatic leukæmia (case 10).

COMMENTS

It was ultimately decided to use the tris(β-chlorethyl) amine hydrochloride almost exclusively for the treatment of the cases in this series, since no serious general or local side-effects were encountered at any time, whereas the bis compound was found by us to produce local tenderness and thrombosis of the veins at the sites of injection.

When the tris compound was given, transient mild toxic effects developed in about half the cases. These effects were for the most part subjective and included headache, nausea, anorexia, and vertigo. Vomiting, with or without relation to food, occurred in 20% of the group and generally appeared about one to five hours after the injection and recurred at intervals of two or three hours until finally passing away after twelve to twenty-four hours. In general these side-effects became less pronounced as treatment proceeded, and in no instance was it necessary to abandon the therapy because of them, though we did interrupt a second course of injections in 2 cases of chronic myeloid leukæmia (cases 4 and 6) for four days when the vomiting was associated with a temporary attack of diarrhœa.

The depressant effect on the total white-cell count appeared as a rule from about the third to the fifth day after the first injection of the tris compound, reaching a maximum from about the tenth to the sixteenth day after the initial course of treatment, which usually consisted of 3–6 injections of 0·1–0·2 mg. per kg. of body-weight.

We have already emphasised that it is essential to control very carefully the whole of the treat-given without difficulty in our outpatient clinics—this is only done when the patient can attend fairly easily and regularly for proper follow-up and hæmatological control of the treatment. This is extremely important, since the potency of these substances and their profound leucopenic effects make it essential to have complete control of the patient during the treatment, with full hæmatological examinations.

CLINICAL RESULTS

Our first series of cases, which included 8 patients with chronic myeloid leukæmia, 3 with chronic lymphatic leukæmia, 4 with Hodgkin's lymphadenoma, and 3 with polycythæmia vera, were treated with these two β-chloroalkylamines and are described here. The ages of the patients ranged from 20 to 68 years. The patients were not specially selected with regard to severity or duration of the disease, and all had been under observation for a control period of not less than four weeks before the institution of treatment and had not received any other form of treatment. They were all admitted to hospital during the initial stages of the investigation, but those showing satisfactory responses were later discharged and kept under close observation in the clinic, where treatment was also given when indicated.

Detailed histories were obtained from each patient, a complete clinical examination was carried out, and the sizes of any palpable masses, such as an enlarged liver, spleen, and lymph-nodes, were carefully determined and photographed for the purposes of comparison before and after treatment. Full peripheral blood-counts were performed usually twice weekly during the hospital period, and a daily total white-cell count was made as routine. Smears of the sternal marrow obtained by aspiration were examined before treatment began and at intervals throughout the subsequent treatments.

Chronic Myeloid Leukæmia

All 8 patients (see table) received the tris compound intravenously; case 4 (fig. 3) was given several courses of the bis compound at one stage, but this was discontinued because of its tendency to produce venous thrombosis at the site of injection. Rhoads (1946) apparently observed this tendency more often with the tris compound, but our experience was to the contrary.

The initial fall in the total white-cell count was satisfactory in 7 out of 8 cases, and in 5 of these 7 cases there was a coincident rise in the red-cell count and percentage. Cases 3 and 5, who did not show improvement in the anæmia, had coincident pernicious anæmia and had responded satisfactorily to treatment with liver and desiccated hog's stomach for some years before the onset of the leukæmia. Case 2 did not appear to respond to the halogenated-alkylamine therapy significantly and had probably received an insufficient dosage.

The size of the enlarged spleens decreased appreciably in 6 cases during the first one or two months' treatment but increased again later, even though the administration of the alkylamine was continued and the total white-cell counts were maintained at satisfactory levels of 20,000–60,000 per c.mm.

In cases 1 and 4 receiving prolonged therapy (four and six months respectively) the response of the di to treatment appeared to become less pronounced and there was a tendency for the total white-cell count to rise in spite of increased doses until finally a refractory stage was reached (figs. 1 and 3).

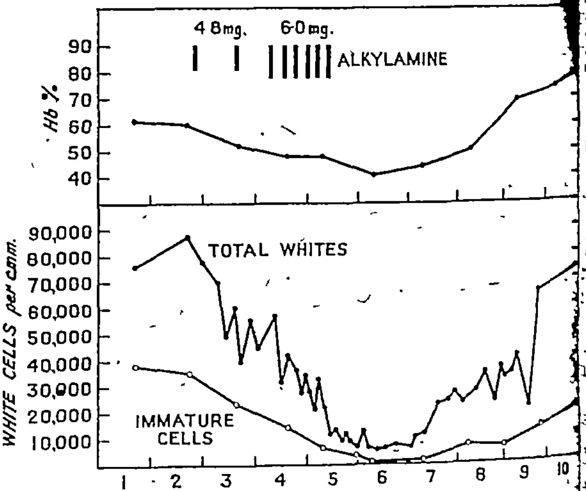

Fig. 2—Chronic myeloid leukæmia (case 3).

There did not appear to be any considerable increase in the expectation of life in 4 of these 8 cases, but case 1 returned to work and lived a fairly normal life for about eight months. When admitted to hospital at the start of treatment he had been bedridden for three months and had been unable to work for a year.

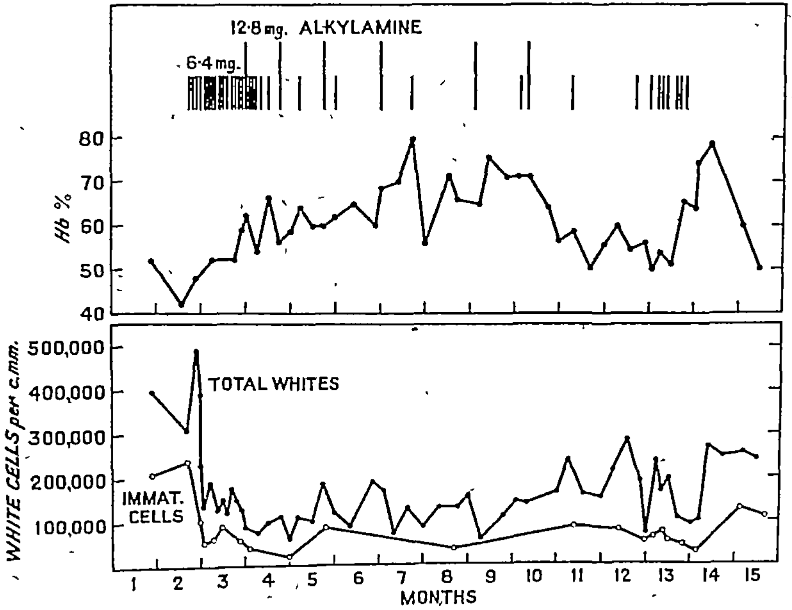

Fig. 1—Chronic myeloid leukæmia (case 1).

Chronic Lymphatic Leukæmia

Three patients (cases 9, 10, and 11) with chronic lymphatic leukæmia were treated with intravenous injections of tris(β-chlorethyl)amine hydrochloride in a similar manner to the cases of chronic myeloid leukæmia. A moderate shrinkage in the enlarged cervical, mediastinal, axillary, and inguinal lymph-nodes took place, and initial satisfactory depressions of the total white-cell counts were observed (figs. 4 and 5), though the treatment produced no significant improvement in the red-cell counts or Hb percentage such as had been seen in the chronic myeloid group. Blood-transfusions had to be given to 2 patients several times throughout the investigation, but none showed much clinical improvement ultimately on this form of treatment, though there

There was considerable variation in the response to treatment in individual cases in all groups but the least satisfactory results were obtained in chronic lymphatic leukæmia.

A dosage of 0·1–0·2 mg. per kg. of body-weight was adopted, and tris(β-chlorethyl)amine hydrochloride was the compound of choice.

Very careful control of every case by frequent examination of the bone-marrow and of the peripheral blood is essential in view of the nucleotoxic and cytotoxic actions of the halogenated alkylamines.

The toxic effects include (1) pain, inflammatory reaction, or even thrombosis at the site of. and immediately after, injection, and systemic effects, lasting up to 4 hours, such as anorexia, nausea, vomiting, diarrhœa, headache, and vertigo; and (2) more serious delayed effects, comprising leucopenia, granulopenia, thrombopenia, or even a severe anæmia associated with aplasia of the bone-marrow. These undesirable toxic effects are avoided by careful hæmatological control of the cases and the adoption of a safe technique of administration.

The two alkylamines do not appear to cure leukæmia or the other conditions mentioned. but in some cases they give relief by reducing the total white-cell count, with a resultant improvement in the anæmia. In other cases embarrassing enlargements of the lymph-nodes, liver, and spleen disappear, leading to an increased feeling of well-being. Improvement is rarely maintained, and the patient's response to this treatment appears to diminish after repeated injections. In Hodgkin's disease the lymphatic enlargement is most dramatically reduced, but the ultimate prognosis is still sub judice.

Investigations are proceeding on new methods of administration and control of this form of therapy. It may be an advantage to use some form of combined therapy or to give different preparations of varying activity on the hæmopoietic organs at certain stages of the disease.

THE RHESUS ANTIGEN C^w

CAUSING HÆMOLYTIC DISEASE OF THE NEWBORN

SYLVIA D. LAWLER M.B. Lond.
J. J. VAN LOGHEM, jun. D.M. Amsterdam

From the Medical Research Council Blood Group Research Unit, Lister Institute, London; and the Centraal Laboratorium van den Bloed Tranfusiedienst, Nederlandsche Roode Kruis, Binnengasthuis, Amsterdam

A RARE Rh antigen, C^w, was described by Callender and Race (1946). A patient at the Radcliffe Infirmary, Oxford, with lupus erythematosus diffusus responded to blood-transfusions by making a succession of "new" antibodies. One of these antibodies was called anti-C^w. The Rh group of the patient was CDe/CDe, and two of the donors were eventually recognised as being C^wDe/CDe. C^w is a form of antigen alternative to C or c; it occurs in the bloods of about 2·5% of English people.

We here report the finding of a second example of anti-C^w, formed this time as a result of immunisation by pregnancy. The mother has never been transfused. The history of her pregnancies is as follows:

April, 1940, infant jaundiced for a month, but recovered.
August, 1941, infant died on third day from icterus gravis neonatorum.
October, 1942, stillborn macerated fœtus.
November, 1943, miscarriage at fourth month.
December, 1944, infant died on third day from icterus gravis neonatorum.
June, 1947, infant died of erythroblastosis fœtalis.

—, no agglutination; w, weak microscopic agglutination; +++, strong agglutination visible to naked eye.

The mother's serum, taken after the birth of the latest child, agglutinated the cells of both father and baby. When the cells were suspended in saline the agglutination was weak, but with albumin suspensions the agglutination was powerful. Of 205 samples of Dutch blood, suspended in albumin, 10 were agglutinated by the serum. The blood-groups of the family at first appeared to be compatible in all respects: mother CDe/cde : O : MN, father CDe/cde : O : MN, child CDe/CDe : O : MN. Nevertheless the presence of the antibody and the history, which was typical of hæmolytic disease, strongly suggested that Rh incompatibility must be present.

The samples of blood from both mother and father were then tested against the serum of the Oxford patient containing the original anti-C^w agglutinin. The antigen C^w was found in the father's blood but not in the mother's; thus a Rh antigen incompatibility was disclosed.

The antibody in the mother's serum was then proved to be anti-C^w by testing its reactions with a panel of cells of laboratory workers previously tested with the Oxford serum. The results are given in the accompanying table.

DISCUSSION

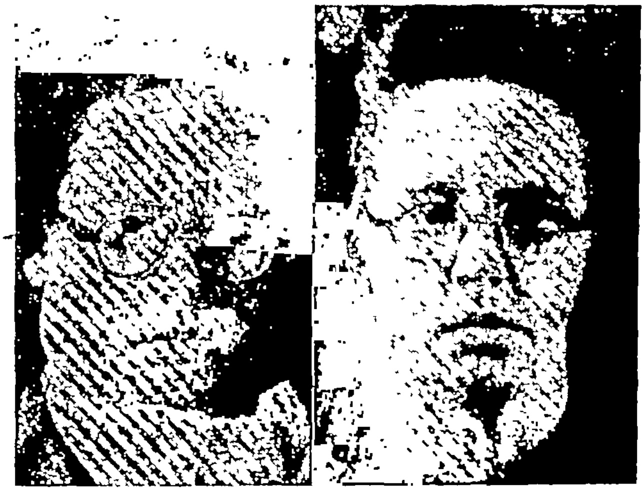
The probability that the agglutination of the 5 C^w bloods out of the 20 is only a chance association is 1 in 15,500, as calculated by Fisher's exact method for 2×2 tables. The Rh groups of the family therefore are:

Mother	..	..	CDe/cde
Father	..	..	C^wDe/cde
Child	..	..	C^wDe/CDe

This case shows some interesting features. Since the father is heterozygous for C^w, the family has been ment by means of daily total white-cell counts, frequent differential counts (particularly the granulocyte percentage), and accurate assessment of the clinical condition and response of the patient.

Microscopical examinations of smears of the bone-marrow obtained by sternal aspiration were of considerable value in assessing the extent of the initial treatment required and in determining the degree of the leucocytic depressant activity at different stages of the investigation. The routine performance of this examination at short intervals decreases the possible dangers of overdosage by the halogenated alkylamines leading to aplastic anæmia, agranulocytosis, or thrombocytopenic purpura.

The earliest manifestation of the toxic effects of the tris compound on the hæmopoietic tissue was usually a lymphopenia of the peripheral blood, followed later by a neutropenia. In 2 cases there was a transient depression of the total platelet-count during the early stages of treatment, but this returned to normal as the anæmia improved. Though the increased hæmorrhagic tendency could be clearly demonstrated by brachial constriction (Hess test), no spontaneous hæmorrhage developed in the skin or from the mucosæ of these patients at any time.



(a) (b)

Fig. 6—Enlarged cervical lymph-nodes in Hodgkin's disease: (a) before treatment; (b) 9 weeks after start of treatment.

The leukopenia persisted for two or three weeks. It was interesting to note that no signs of bacterial infection arose in 2 cases in which the total number of white cells fell below 2000 per c.mm. for periods of one to three weeks. The typical agranulocytic syndrome was not seen in any of the present cases.

Figs. 1–3 showed that there was a sharp fall in the total number of circulating immature white cells in the myeloid leukæmic cases which was coincident with the fall in the total white-cell count as treatment proceeded. Similar hæmatological effects were observed in Hodgkin's disease, and a severe leucopenia developed in 1 case while the clinical improvement and subjective sense of well-being were becoming most manifest. No ill effects arose as a result of the leucopenia, and the total white-cell count returned to normal after four weeks.

During the early stages of treatment the most prominent effect on the appearance of the bone-marrow was a reduction of the mitotic activity of the young proliferating cells, especially the leucopoietic series at first and all elements later, until a final appearance approaching almost complete aplasia was obtained.

Detailed macroscopical and microscopical examinations were carried out on the organs of patients coming at later dates to necropsy, and photographic records were made for comparative purposes. The [illegible] appearances of cross-sections of the bone-marrow [illegible] spleen from 2 cases of chronic myeloid leukæmia [illegible] striking. The usual greyish infiltration of these tissues characteristically seen in the untreated case was not present, the marrow appearing deep red throughout and the spleen normal. It was impossible to make any diagnosis on the macroscopical findings alone, and the microscopical examination of various organs often did not reveal the typical pathological picture of the leukæmic proce These necropsy findings tended to vary according the time which had elapsed after the cessation treatment. When the alkylamine therapy had be continued up to the time of death and had been associat with a satisfactory depression of the total white-c count, *the only signs of leukæmia* found were a fe scattered primitive blood-cells in the liver, spleen, an bone-marrow. The more typical lesion of myeloid o lymphatic leukæmia was observed when treatment ha not been given for several weeks, though the appearance of certain of the immature cells was such that their exact nature could not be determined. These cells may possibly represent a recovery reaction of the hæmocytoblasts from the depressive effect of the alkylamine.

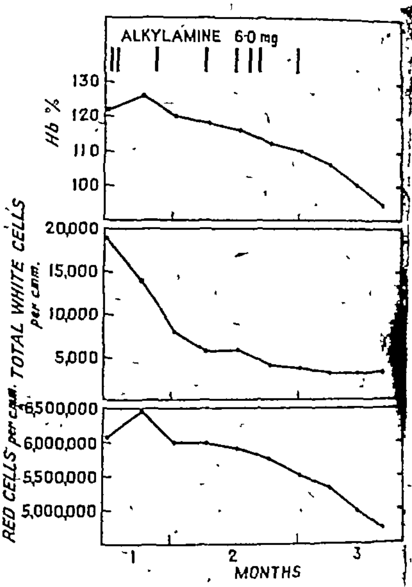


Fig. 8—Polycythæmia vera.

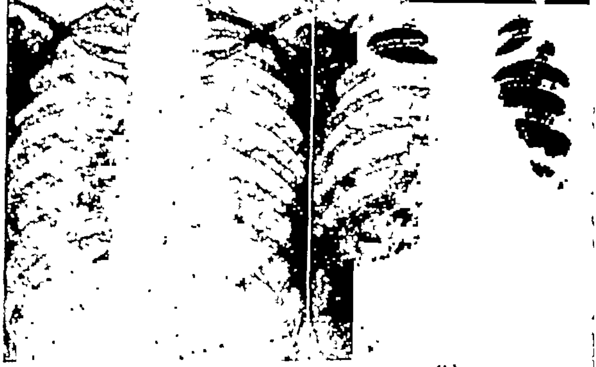
SUMMARY

The results of treatment with intravenous halogenated alkylamine (nitrogen mustard) in 18 cases of chronic myeloid and lymphatic leukæmia, Hodgkin's disease, and polycythæmia vera are described. Diagnosis was confirmed by biopsy of lymph-nodes or of sternal marrow.

The most beneficial effects were observed in chronic myeloid leukæmia, though dramatic improvement also occurred in Hodgkin's disease.



(a) (b)

Fig. 7—Radiograms showing densities of right hilar and mediastinal shadows in Hodgkin's disease: (a) before treatment; (b) 9 weeks after start of treatment.

Nutritional safety

during weaning

As the infant's introduction to solid food, and as a basis of the diet during the subsequent months, there is no more suitable preparation than Farex. The usual starchy predominance of cereals is balanced in Farex by an increased proportion of protein: in addition, Farex supplies minerals — assimilable iron, calcium and phosphorus — and a useful amount of vitamin D (1,000 i.u. per oz.). With Farex and milk as the staple ingredients, weaning to solids is reduced to its simplest and safest terms. Please help to ensure sufficient Farex for weanlings by prescribing it only for them.

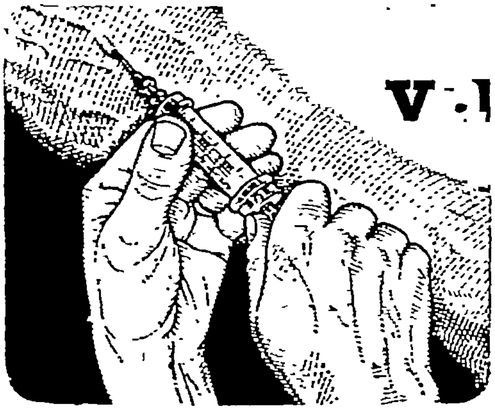
GLAXO LABORATORIES LTD GREENFORD · MIDDLESEX · BYRon 3434



varicose veins

the most **efficient**
injection treatment

'Ethamolin' offers specific advantages over any other sclerosing agent for varicose veins. Given sufficiently early, 'Ethamolin' frequently brings *lasting* benefit; marked relief can be obtained even in cases of prolonged untreated varicosity. 'Ethamolin' forms a firm, adherent thrombus. Sloughing is not caused if the solution escapes around the vein and there are no general reactions except in the very rare case of hypersensitivity. The total dosage required is normally less than 6 cc; being powerfully bactericidal, 'Ethamolin' reduces the risk of infection to a minimum.

With 'Ethamolin' the practitioner is thus equipped to deal with the majority of his varicose patients without need to resort to operative measures.

2 cc Ampoules: Boxes of 6 and 100.
Bottles of 15 cc and 30 cc.

GLAXO

ETHAMOLIN

Brand of MONOETHANOLAMINE OLEATE

GLAXO LABORATORIES LTD., GREENFORD, MIDDLESEX. BYRon 3434 unfortunate not to produce either cde/cde or CDe/cde children who would have escaped the disease. If it had not been possible to test the bloods with the original anti-C^w serum, the Rh incompatibility and therefore the cause of the hæmolytic disease would not have been revealed. It would probably have been concluded that the disease was due to some hitherto undescribed blood-cell antigen-antibody reaction, since the ABO and MN groups are in this case compatible.

The antibody is in the incomplete or hyperimmune form, the reactions in saline being weak, but with albumin suspensions the agglutination is visible, and the serum also gives a positive indirect Coombs's test after incubation with C^w cells. This is interesting in view of the period of time during which the woman has been immunised, as shown by the history. Diamond (1947) expressed the view that the antibodies which produce agglutination with saline suspensions are the first to be formed, and that, if immunisation continues, hyperimmune antibodies, reactive in albumin, are produced.

The frequency of the antigen C^w in Holland reported here (10 in 205 samples of blood, or 4·9%) is higher than the English frequency, which is 2·5%. Though the difference is not quite significant statistically, in a larger sample it would probably be so, for tests on bl samples from Norway (Hartmann et al. 1947) and from several other European countries (unpublished records M.R.C. Blood Group Research Unit) show that the frequency of the antigen C^w on the mainland of Europe is significantly in excess of that in England.

SUMMARY

An example of the rare Rh antibody, anti-C^w, resulting from immunisation by pregnancy and causing hæmolytic disease of the newborn is described.

This is the second anti-C^w serum which has been found. The first was formed as a result of immunisation by blood-transfusion.

The antigen C^w was found in 10 out of 205 samples of Dutch blood.

We are indebted to Dr. J. M. Soeters, of Breda, Holland, the pædiatrician who was consulted in this case, for having sent us samples of blood and for permission to publish the history of the pregnancies.

Reviews of Books

Nutritional Disorders of the Nervous System

John D. Spillane, B.Sc., M.D., M.R.C.P., assistant physician and neurologist, Cardiff Royal Infirmary. Foreword by George Riddoch, M.D., F.R.C.P. Edinburgh: E. & S. Livingstone. 1947. Pp. 280. 20*s*.

Dr. Spillane was adviser in neurology to the Middle East Forces, and in this capacity he made a detailed clinical study of the disorders of behaviour which were seen in prisoners-of-war. He followed up this work later, and the present volume, which is based on his personal investigations, includes accounts of disorders seen in Europe and in the Far East, as well as in his own theatre of war.

The main importance to many of us of these unnecessary diseases is that they have affinities to other naturally occurring disorders, of which the primary optic atrophies, polyneuritis, and some disorders of behaviour may be examples. In this monograph are found in their most complete forms disorders which are seen as fragmentary syndromes and consequently not necessarily recognised under less rigorous conditions. Dr. Spillane has given a full survey of the present knowledge of the chemistry and pharmacology of the vitamin-B complex and has then devoted a chapter to a descriptive account of the major deficiency disorders. In consequence the first eight chapters of the monograph are in effect critical reviews of the published work, each ending with an extensive bibliography. His personal experiences make up the second half of the book and his case-reports are wisely confined to an appendix. He has documented this section with charts, tables, and photographs of patients and histological preparations. In the evaluation of his data he has shown conservative respect for our ignorance of the physiological action of the vitamin-B complex in the peripheral and central nervous systems. Those who associate this subject with confusion and jargon will find that Dr. Spillane always makes a clear statement in the most pleasing of phrases.

Management of Common Cardiac Conditions

Editor: W. G. Leaman, jun., M.D., F.A.C.P., professor of medicine, Women's Medical College of Pennsylvania. London: J. B. Lippincott. 1946. Pp. 306. 24*s*.

This book is a reprint of articles on the cardiovascular system which appeared in *Clinics* in June, 1946. The 24 American contributors give concise accounts of recent developments in the diagnosis and treatment of cardiac and vascular disease which the practitioner should know. In a review of surgery of the heart the topical subjects of ligature of the ductus arteriosus, the Taussig-Blalock operation for Fallot's tetralogy, and the surgical treatment of coarctation of the aorta are briefly described, among other procedures. A sound article is contributed by L. N. Katz and L. G. Kaplan on the meaning of the electrocardiogram and its value to the general practitioner, in which both the field of usefulness of this method and its limitations are indicated. Cardiac pain is very shortly considered in a section on the treatment of acute cardiac infarction and at greater length in comments on chronic coronary disease. A chapter on the medical treatment of hypertension is of theoretical interest, but the reader will probably conclude that the outlook for hypertensives has not been much altered by the new methods of treatment. There are one or two statements which will need to be reconsidered—for example, that intravenous ouabain may be given if digitalis has not been given during the previous 48 hours; and that the pulmonary arterial pressure is not yet measurable (this, of course, has now been accomplished by means of the intracardiac catheter). Nevertheless, the practitioner will find this book well worth consulting for information on recent developments in the treatment of cardiovascular diseases and their underlying principles.

Hey Groves's Synopsis of Surgery (13th ed. Bristol: J. Wright. 1947. Pp. 637. 25*s*.).—For this latest edition Sir Cecil Wakeley has added a chapter on penicillin and the sulpha drugs; and he has made space for a record of the rapid progress in the various specialist branches of surgery. For revision and reference students and practitioners can still turn with confidence to this compact work.

The Earth's Green Carpet (London: Faber and Faber. 1947. Pp. 219. 8*s*. 6*d*.).—If anyone should be heard for much speaking it should be the School of Organic Farming and Gardening; for despite paper shortage and other troubles, book after book appears on the importance of composting vegetable and animal dejecta (including human) by the Indore process. The authors quote each other; and in this book Lady Howard follows the tradition, implying that most diseases that afflict plants, and some which afflict men, would be wiped out if agriculturists would prefer compost to artificial manures; caterpillars would not devastate the cabbages and currant bushes, and people and animals fed on compost-manured vegetables and cereals would achieve sound teeth and bones, and reap abundant health. There is, of course, much to be said for the Indore process. But from this and similar books one would hardly gather that the science of composting vegetable refuse was put on a firm foundation at Rothamsted before 1921; nor that the value of humus in the soil was appreciated, the amount of nitrogen and phosphorus lost from the soil by turning sewage into the sea was deplored, and soil erosion was studied by others before the followers of this school.

Social Pathology of Stillbirth

Few would have been surprised if the domestic stresses and deprivations of a total war had been reflected in a rising tide of infant mortality ; that such a movement was both avoided and reversed was one of the medical triumphs of the war. The fall achieved in the death-rates among infants was accompanied by an acceleration in the pre-war downward trend in the stillbirth-rate This trend was observed in both male and female births, legitimate and illegitimate, born to mothers of all ages and at all parities; and the universality of the improvement suggests that general social or environmental factors were operating to effect it. A closer analysis reveals, however, that the social correlations seen in infant mortality do not appear so clearly in the fœtal or neonatal death-rates. The gradient between the social classes in infant mortality is roughly twice as steep as the same gradient in the stillbirth and neonatal death-rates, while the stillbirth-rate before the war was lower in the poorer crowded districts of London than in the more affluent boroughs.[1]

Some at least of the discrepancies in the relations between social conditions and infant and fœtal mortality are explained by the biological factors of age and parity. Stillbirths are more frequent in older mothers, particularly with their first-born, and at all ages the stillbirth-rate, after falling to a minimum at the second birth, rises steeply with succeeding pregnancies. People in social classes I and II—the professional, higher commercial, and managerial section of the community—tend to marry and procreate rather later in life than those in the artisan and labouring classes (III, IV, and V). The advantages to the former group which accrue from their better environment are thus in part countered by the handicap of bearing children when the first bloom of youth is past. This biological masking of the social differences thus merely accentuates the need for studying the economic background of fœtal mortality. One line of approach has been almost entirely statistical, and **Sutherland**[2] has shown by multiple regression technique that the stillbirth-rate is related, in the county boroughs, to the degree of unemployment and to the proportion of poorly paid workers, but not to overcrowding; in the administrative counties, on the other hand, unemployment alone seems to be correlated with the stillbirth-rate. By similar means, **Woolf**[3] has demonstrated an association between the stillbirth-rate and indices of economic stringency. As **Sutherland** points out, such correlations do not account for more than part of the total variability in the stillbirth-rate between different parts of the country, and the effects of antenatal care and obstetric skill should not be neglected because they cannot be readily measured.

The results of statistical studies of this type are, as their authors are well aware, not easy to interpret because of the difficulty of determining whether poverty exerts its influence directly by the restricted diet it entails or whether some of the inter-class differences are due to factors such as intelligence, which in a competitive society is correlated with economic status. In a previous paper on the closely related subject of infant mortality **Baird**[4] suggested that poverty is important not only in imposing a poor diet during pregnancy but in acting throughout life to stunt and deform by prolonged malnutrition the frames of the mothers of the working-classes, so that labour is often premature, long, and difficult. Even when the standards of obstetric care are similar, and even when, as in these days of rationing, dietetic standards converge, the aftermath of a life of insufficient feeding may be reflected in the raised infantile and maternal mortality-rates in the poorer classes. On another page **Baird** complements his previous work by a study of the social background of fœtal mortality in groups of nursing-home and hospital patients under specialised supervision. He shows again that the biological factors of age and parity do mask the social gradients in neonatal and prenatal death-rates. These gradients could not be explained by grossly different standards of specialised supervision, and it was significant that the main disparity between the two social groups lay in the relative frequency of stillbirths associated with toxæmia or without apparent cause, and in the neonatal mortality among the unduly high proportion of prematurely born infants in the poorer classes. Indeed, as is shown in the distribution of deaths by cause given by the Registrar-General for Scotland, where a diagnostic label is required on certification, the fall in stillbirths from 1939 to 1944 was most pronounced among the group of "ill-defined and/or unknown" causes. There is some experimental evidence to support the contention that this group of causes is influenced by diet, and **Baird**'s work has an advantage over purely statistical studies in that, by clinical assessment, he established that there were differences in stature and physique between the contrasted social groups. These differences, presumably dietetic in origin, determined the better reproductive performance, despite the handicap of age and parity, of women from the higher social classes. Further, it was noted that even during the war the diet consumed by the women of social classes I and II was appreciably better than that of their poorer sisters. **Baird** also stresses the importance of specialist attention by contrasting the stillbirth-rate of 17 per 1000 among primiparæ belonging to social classes I and II and treated privately by consultant obstetricians (a sample likely to be biased in favour of the potentially complicated case) with the national

TRADE MARK

'THIAZAMIDE'

BRAND

sulphathiazole

Sulphathiazole is one of the most active of the sulphonamide drugs at present available for the treatment of pneumococcal, meningococcal, gonococcal and haemolytic streptococcal infections. It is the sulphonamide of choice for the treatment of urinary tract infection, staphylococcal infections and gas gangrene. It is an effective chemotherapeutic agent in acute bacillary dysentery and in chancroid.

Supplies:
tablets of 0.125 Gm.
and 0.50 Gm.
also available in cream,
paste, eye ointment
and powder

'SOLUTHIAZOLE' brand neutral soluble sulphathiazole derivative is recommended when parenteral administration is indicated.

May & Baker's sulphathiazole preparations are protected by British Patent No. 533,495, which was granted on 24 May, 1946, jointly to May & Baker Ltd., and Ciba Ltd. of Basle.

FOR SCABIES!

'Proscabin' of course ✓

Benzyl benzoate treatment of scabies has clearly demonstrated its advantages of efficacy and convenience.

'Proscabin' is the "Bayer" benzyl benzoate emulsion. It is an elegant preparation with little tendency to irritate the skin.

One treatment (two consecutive applications) is usually sufficient. Instruction-cards for handing to patients are supplied on request.

f riboflavine, biotin, pyridoxine, pantothenic acid, nd nicotinic acid. In the great majority of cases the hibition is reversed by the presence of the vitamin n appropriate concentration. Competitive analogues f this kind should find uses in the treatment of on-infective disease. For example α-tocopherol-uinone, an analogue of vitamin E, interrupts regnancy in mice, and analogues of thyroxine might e useful in hyperthyroidism.

So far the chief aim of work with analogues has een to obtain efficient antibiotics—analogues which ock essential metabolic processes in parasites without affecting the hosts are required. Of two analogues f nicotinic acid (pyridine-3-carboxylic acid), pyridine-ulphonic acid which inhibits the growth of bacteria t does not affect mice is more promising than cetylpyridine which has no effect on bacteria t causes a vitamin deficiency in animals. Similarly enylpantothenone is inhibitory in micro-organisms t not in animals. It has a curative action in bird alaria,[5] for which it was tried after it had been served that pantothenic acid is essential for the rvival of the malaria parasite in vitro. Before at, McIlwain and Hawking[6] had protected mice ainst streptococcal infection by blocking panto-enic acid with pantoyltaurine. Many analogues of ino-acids and purines essential for the growth f bacteria have been prepared, and some of them are wth-inhibitors. The antagonism between naturally rring amino-acids, such as arginine and lysine, e examples of competitive inhibition.

Competitive analogues should prove a valuable tool biochemical research, for their power to interfere ecifically with one process in a complex metabolic ain should help to elucidate the reactions. A cent illustration of the wide influence of these ideas ses from the discovery that chicken red cells have carbohydrate reactor to which influenza virus taches itself in causing hæmagglutination. Pectin, esumably a structural analogue of the carbohydrate, as found to prevent the hæmagglutination, and rthermore to prevent the multiplication of the rus in chicken embryos.[7] The theory of biological mpetition provides a rational explanation for some der observations. Thus it has been shown that the x of certain algæ is determined by the ratio of - and *trans*-dimethylcrocetin they contain. This is esumably a case of competition for sex-determining ntres. It may be that sex phenomena in higher imals are based on similar competition between strogens and androgens, which are structural ana-gues and occur together in every individual. The asis of the theory is the power of an analogue to splace its metabolite from an active surface, but ly a few definite examples of this are known. hysostigmine, which antagonises acetylcholine, can isplace it from combination with choline esterase. otin sulphone is able to free biotin from combina-on with avidin. If carbon monoxide is considered s a structural analogue of oxygen its action in dis-lacing the latter from hæmoglobin is another example.

Up to now the concept of competitive inhibition as been disappointing in its practical results. No portant antibiotic has emerged from the hundreds of structural analogues so far produced (sulphanilamide was not a result of the theory, but vice versa). However, the theory is young, and it may yet produce another sulphanilamide or penicillin. It has captured the imagination of scientists, and has resulted in an immense amount of work being done on the production of structural analogues. It has directed biochemical thought to a rational explanation of drug action, and it has lifted chemotherapy from its state of hit or miss. There are signs generally that biophysicists, chemists, and medical men are combining to tackle those vital problems of the cell on which further progress in chemotherapy, including that of cancer, depends.

Hypoglycæmia after Partial Gastrectomy

PARTIAL (or subtotal) gastrectomy as a remedy for peptic ulcer is an unphysiological procedure. The relief it brings to most patients may well justify its use as a palliative measure: but there is a tendency for the enthusiastic surgeon, and, on occasion, physician, to forget that such radical removal of an essential part of the digestive system must carry some disadvantages and risks. American reports[1,2] show that, among 579 cases of gastrectomy, 89, or 15%, had postoperative disturbances; and the commonest disturbance was hypoglycæmia.

That carbohydrate metabolism may be deranged after gastro-enterostomy, and also in cases of duodenal ulcer, has been known for some time.[3,4] The disturbance consists primarily of a temporary hyperglycæmia, resulting in glycosuria; and LAWRENCE[3] was able to reproduce the condition in healthy students by intubation and introduction of glucose into the duodenum. Sometimes hyperglycæmia was followed by temporary hypoglycæmia; for this state LAWRENCE prefers the name "oxyhyperglycæmia" to the original one of "lag-storage curve" proposed by MACLEAN. It is usually ascribed to abnormally rapid emptying of the stomach with a correspondingly rapid absorption of glucose. Three questions, however, remain unanswered. In the first place, why should such a hyperglycæmia be followed by hypoglycæmia? Secondly, what is the relationship between the hypoglycæmia and the symptoms of which some partially gastrectomised patients complain? And finally, what is the incidence of hypoglycæmic reactions in such patients? As Dr. BARNES points out elsewhere in this issue (p. 536), the possible answers to the first of these questions are: (1) the patient may respond to the hyperglycæmia by secreting an unusually large amount of insulin; (2) he may become abnormally sensitive to his own insulin; or (3) there may be failure of adrenaline secretion in response to the rapid fall in blood-sugar after the hyperglycæmia. On the basis of insulin-glucose curves and adrenaline-sensitivity tests, BARNES suggests that increased sensitivity to insulin from the recurrent hyperglycæmia is the main factor. This may well be so; but one of his arguments against increased secretion of insulin is of doubtful validity: it is that after the introduction of glucose into the duodenum of normal

figure of 37 for these classes. The same results do not appear, however, in similar comparisons between the rates for patients of the remaining social classes treated by specialists in hospital (37), and the national average for the same social classes (39·7).

These comparisons may not be strictly between like and like, but they indicate the complexity of the problem. Both the inadequate diet which poverty entails and the lack of skilled attention or the failure to make full use of specialist advice appears to be involved in the causation of stillbirths. No doubt raising the standard of living among workers would, if it improved the diet, bring about both short-term and long-term reductions in fœtal mortality, but as yet the argument in favour of an entirely economic or nutritional explanation of its causation is indirect, and only a properly controlled field study of the environmental circumstances of stillbirth can carry conviction. To attain balance and accuracy in the final assessment of their relative contributions to the background of fœtal mortality such a study must include, as **Baird** has shown, not only the economic factors, such as work during pregnancy and the proportion of the family income spent on food, but also the personal characteristic of physique and intelligence and the use made by the mother of specialised services and advice.

Biological Competition

A CONCEPT has grown up in the last few years which is as striking as **Ehrlich**'s lock-and-key theory of immunity of a generation ago and of even wider application—that of biological competition. This idea, whose importance and universality were first emphasised by **Fildes**[1] and **Woods**[2] in 1940, arises from the present-day picture of an enzyme. The enzyme is regarded as possessing an active centre whose groups are arranged in a definite configuration which determines its specificity. It can adsorb, activate, and then metabolise only a substance which fits this active centre exactly—that is, only its specific substrate. There are however substances called analogues, usually derived from the natural substrate by a slight change in constitution, which are similar enough in shape to the substrate to be loosely held by the enzyme but do not fit well enough to react further. These compete with the natural substrate for the enzyme surface, and according to their concentration and affinity for the surface may occupy part or all of it, so slowing down enzyme action or stopping it altogether. In such a system enzyme action can be hastened by adding substrate (metabolite), or further slowed by adding more analogue (inhibitor). In other words, the inhibitory effect is reversible; it is proportional to the ratio between the activities of the two substances rather than to the concentration of the inhibitor, and this is characteristic of biological competition. The inhibition ratio is usually constant for each pair of antagonists, and, since the natural metabolite has the greater affinity for the enzyme, many molecules of inhibitor are needed to antagonise one molecule of metabolite.

As early as 1910 it was shown that the action of amylase on starch was inhibited by other carbohydrates, and in 1927 **Quastel** and **Wooldridge**[3] founded the modern theory with their study of the inhibitory effect of fumaric acid on succinoxidase. **Clark**,[4] in 1937, suggested that the action of drugs was the result of their competition with similar natural substances. But it was **Fildes** and **Woods** who, in their theory of sulphanilamide action, stated the concept clearly and captured the imagination of scientists with that most striking example of biological competition. They postulated that *p*-aminobenzoic acid was essential for the metabolism of micro-organisms (an "essential metabolite"), and that sulphanilamide owing to its structural similarity competed with it for an enzyme surface. The prediction that *p*-aminobenzoic acid is an essential metabolite has been confirmed, and recent work suggests that sulphanilamide acts by interfering with the synthesis of folic acid from *p*-aminobenzoic acid. All living things, it seems, require certain dietary factors besides actual foods in order to live, and there is a close correspondence between the essential metabolites of bacteria and the vitamins of higher organisms. The effect of a small change in the structure of one of these essential factors cannot yet be predicted; the analogue may have a weak vitamin potency, be inert, or act as an antagonist. If metabolic activity persists after a small change, a greater change may produce an antagonist. Thus, substitution of an ethyl group for the methyl group of thiamine gives a substance with a weak thiamine potency, whereas substitution by a butyl group produces an antagonist. Two methods which are usually successful in yielding antagonists are the conversion of a carboxylic acid to a sulphonic acid or to a ketone, and the substitution of oxygen, nitrogen, carbon, or sulphur atoms for each other in a ring system. Some analogues—for example, *p*-aminobenzamide—inhibit or stimulate according to the conditions present. Desoxypyridoxine competes with pyridoxine in the chick, has no action in the rat, and has a vitamin action in lactobacilli. These anomalies may arise from the power of some organisms to break down or change an inhibitory analogue. A metabolite may have several functions, and different structural analogues may interfere with different processes. By choosing the appropriate analogue it may be possible to obtain the required properties.

Inhibitory analogues produce symptoms of deprivation of the metabolite, and, since these are most striking in the case of vitamins in animals and of essential metabolites in micro-organisms, these types have been most investigated. Inhibitor analogues to practically all the vitamins are known There are many thiamine analogues, the best known of which is **Woolley**'s pyrithiamine, in which the thiazole ring is replaced by a pyridine ring. This causes thiamine deficiency in animals and inhibits the growth of moulds, yeasts, and bacteria which require an external supply of the vitamin. Gluco-ascorbic acid antagonises vitamin C and causes scurvy in guineapigs Many naphthaquinone derivatives are inhibitory analogues of vitamin K. There are several inhibitory analogues

readily reinfected by the virus used on the first asion, as well as by different material. Other experi- ntal work of this kind by Toomey [6] indicates however t sublethal infection with certain virulent strains of us will protect monkeys against subsequent attempts infect them with other presumably less virulent ins. Among the puzzling results of human sero- ical investigations in poliomyelitis are the not uncom- n failure to find protective antibodies in the serum convalescents, and the frequent observation of such ibodies in the sera of older persons who have not l an obvious clinical attack. Some of these findings y be explained by antigenic differences between ious strains of the virus. It seems probable that re is a poliomyelitis group of viruses within which re are immunological variations, not unlike those nd in the group which cause human influenza. The ution in the laboratory or elsewhere of these problems uld contribute a great deal towards a better under- nding of the epidemiology of the human disease.

CHOLERA IN EGYPT

HE cholera which has broken out in Egypt during last few weeks concerns all nations engaged in ritime trade to the west of the Suez canal. The report the UNRRA Health Division [7] on the cholera situation ring the summer of 1946 deplored the paucity of ormation about the prevalence of the disease through- t the Far East, but remarked that "there has been case of cholera west of India since 1931, apart from Afghanistan-Iran outbreak of 1938–39." The well- n tendency of cholera to spread along trade and rim routes was largely checked for many years, t during the late war its incidence in the Eastern cupied countries rose sharply, and there were con- erable outbreaks in areas previously free for many ars. In 1946 there was one of the most extensive tbreaks ever recorded in China and the Far East.

Cholera's home is India, more particularly in the eas of Bengal, Madras, and Bombay. Epidemics further eld, such as those in the larger seaports of this country ortly after the middle of the last century, have been oided as a result of efficient quarantine and control. important factor in Indian epidemics has been the ass movement of pilgrims to the innumerable fairs and igious festivals. Under suitable climatic conditions ere is grave danger of outbreaks in pilgrim camps; t, still worse, the movements of pilgrims are responsible the carriage of infection to fresh communities, some- nes overseas. The migration of large numbers of fugees, such as that taking place in India at present, s almost invariably been associated with devastating idemics of cholera, and these are aggravated by alnutrition and physical hardship. The pilgrim traffic om the Mohammedan countries to Mecca, possibly more an any other agency, has disseminated the disease om its natural home, and it is possible that the infection s been conveyed by this means to Egypt. Although e Egyptian epidemic has received much publicity— e are informed that about 100 new cases are found daily -it cannot be compared in magnitude to the great tbreaks which, unfortunately, are commonplace in dia and in China. With the bottle-neck of the Suez nal between the eastern and western worlds, however, e strategic importance of Egypt in public health is vious. The climate at certain times, and the dense pulation living under insanitary conditions in the Nile sin must render the appearance of cholera there a urce of constant apprehension. It is indeed somewhat rprising to find that the last important epidemic curred some sixty years ago; the successful blocking of the westward spread of cholera from the highly endemic foci of India and China westwards has been no mean achievement in public health. What course the present epidemic may take remains to be seen. The concentration of the resources of the Western world in combating the outbreak is likely to ensure its early limitation and ultimate elimination, more particularly since the infection really flourishes only in more tropical climates; in temperate and subtropical countries it tends to be self-limiting.

Treatment is still unsatisfactory, for there is no specific cure for the established infection; repair of the gross fluid and mineral loss, on a physiological basis, remains the foundation of hopes for recovery in severe cases. The sulphonamide drugs, either those feebly absorbed, such as succinyl, sulphathiazole, or sulphaguanidine, or of those freely absorbed, such as sulphadiazine or sulphamezathine, are not curative as they are, for example, in the bacillary dysenteries. Nevertheless, in substantial dosage they appear to shorten the course of cholera and possibly modify its severity. Prophylactic immunisation with cholera vaccine is a contributory means of personal prophylaxis; but the duration of what protection it affords is brief, and so it must be given at frequent intervals throughout the period of risk. The control of an epidemic rests fundamentally on prompt and efficient segregation of all suspected cases and contacts, and on efficient sterilisation of their highly infected discharges. The rigid protection of all water and food-supplies from possible contamination with infected fæcal material—the ultimate source of infection in every epidemic—is obviously of major importance. From Cairo comes news that the city and its suburbs are being sprayed with D.D.T. in an attempt to reduce the number of flies.

CONGENITAL AORTIC COARCTATION

ON Sept. 26 Prof. Alfred Blalock, of Baltimore, delivered a Moynihan lecture at the Royal College of Surgeons to an audience of well over a thousand. For those who could not find a place in the lecture-hall he gave a further demonstration immediately afterwards. The address was on congenital cardiovascular defects, but was mainly concerned with aortic coarctation.

Before Dr. Blalock began operating for coarctation of the aorta a considerable amount of experimental work had to be done to see how the stricture in the aorta could be by-passed and an adequate blood-flow provided to the descending aorta below the narrowing. It was found in dogs that if the aorta was divided the left subclavian artery could be turned downwards and joined to the distal segment in such a way that a normal circulation was maintained. An alternative method of dealing with the coarctation was introduced by Crafoord, who actually resected the stenosed area and performed an end-to-end anastomosis between the divided ends of the aorta. This is the method which Dr. Blalock has followed on 11 occasions. He showed a cinematograph film of the operation which also demonstrated the essential clinical features of the condition.

The patient was a young woman in whom the raised blood-pressure in the arms and reduced tension in the legs was clearly illustrated, as also the enlarged superficial collateral vessels. Radiographically the notching of ribs due to pressure erosion from tortuous and dilated intercostal arteries was well marked. The approach was made through a left posterolateral thorectomy with resection of a length of the 5th and back ends of the 4th and 6th ribs. As might be expected from the presence of collateral channels, there was considerable bleeding during incision through the chest wall. The lung was then displaced and the aorta identified. The coarctation was well defined not only by a narrowing but by an area where the violent pulsation of the aortic arch and

Stowman, K. Cholera Situation, Summer, 1946. UNRRA *Epid. Inf. Bull.* 1946, 2, no. 16.

subjects no comparable hypoglycæmia is observed. The blood-sugar of patients with a normal blood-sugar curve may fall as low as 55 mg. per 100 ml. $1^1/_2$–2 hours after glucose, without symptoms.[5] It should not be forgotten that the actual blood-sugar level is only one of the factors determining the onset of hypoglycæmic symptoms; the rate of fall and extent of fall are among the other factors.

The data on which to base the answer to the second problem are still conflicting. BARNES has established a fairly direct time-relationship between the hypoglycæmia and the occurrence of symptoms in his patients, but in GILBERT and DUNLOP's[2] series the time-relationship is not so clear; in both the cases they record in detail symptoms coincided with the period of hyperglycæmia and not with that of hypoglycæmia. On the basis of their findings in 14 cases, ADLERSBERG and HAMMERSCHLAG[6] subdivide the "postgastrectomy syndrome," as they call it, into early and late postprandial types. The early type, which is relieved, partially at least, by rest in the horizontal position and small frequent meals (and which presumably corresponds to the "dumping" syndrome of some writers), they attribute to mechanical factors: these are the small stomach, the rapid emptying of the stump, the rapid filling and emptying of the jejunum, and the subsequent mesenteric irritation. The late type, which is relieved by the ingestion of food, they attribute to hypoglycæmia. This classification is not accepted by GILBERT and DUNLOP, who argue that hypoglycæmia explains the whole syndrome. Yet another hypothesis is that of GLAESSNER,[7] who attributes the early postprandial symptoms to hyperglycæmia; but there is little evidence that hyperglycæmia per se can produce the characteristic upper abdominal discomfort and occasional vomiting.

Much further work is clearly required to elucidate the cause of this syndrome. It should also be possible to establish exactly how often the complication arises and how it is best avoided. No systematic study of this sort has yet been recorded, but observation of the syndrome after 17 out of 45 consecutive gastrectomies[2] suggests that the incidence is by no means negligible. On the question of prophylaxis, opinion is divided. Thus in BARNES's series, when the retrocolic Polya anastomosis was abandoned in favour of a modified Hofmeister type of anastomosis, no further case was noted after over a hundred operations. GILBERT and DUNLOP, on the other hand, concluded that there was nothing to choose between these two procedures. On the treatment of the established syndrome there is greater unanimity. The usual procedure is to give a high-fat, low-carbohydrate diet, or alternatively to give 1 oz. of olive oil before meals. GILBERT and DUNLOP recommend also six small meals daily instead of three larger ones, and they have found that ephedrine gr. $^1/_2$ half an hour before the three main meals is of value. Sometimes the condition tends to improve as time goes on. Whether, as ADLERSBERG and HAMMERSCHLAG suggest, there is a psychoneurotic element in the condition is one of the many unsolved riddles in this intriguing complication of modern gastric surgery.

CONVALESCENT HOMES IN THE NATIONAL HEALTH SERVICE

THE position of convalescent homes in the National Health Service has been in doubt—will they be taken over by the Ministry of Health, like hospitals, or left outside. The Ministry's policy seems to be to indicate which homes could legally be included in the service, and to leave the regional boards to make the final The Ministry has now sent each board a list of homes divided into those "apparently liable" to be transferred to the service, and those whose fate is still under investigation. The former homes may, if they choose, apply to be disclaimed.

It is not obvious from the list what principle is being followed in making this distinction. Some of "apparently liable" homes give no treatment, and the precedent of the homes owned by the Birmingham Hospitals Saturday Fund,[1] would not be liable. The Ministry is at a disadvantage in not being able to visit all the homes, and about many of them only sketchy information is available. The regional boards have nine months to decide which homes to disclaim, and it is to be hoped that no decision will be made without a visit.

It is noticeable that the homes which came under the Ministry of Education by the Education Act of 194 are left alone, except for the few which are long-term children's hospitals in all but name. There is a risk that merely because they have school-teachers on their staff these homes, which are primarily for convalescents, will be excluded from medical supervision, since the of Education inspectors, on their rather infrequent are concerned only with the educational aspect.

SECOND ATTACKS OF POLIOMYELITIS

IT is commonly assumed that an attack of poliomyelitis with paralysis confers a life-long immunity. In 1930 Still[2] noted that what appeared to be second attacks of the acute disease were occasionally reported, but he regarded many of them, occurring within four months of the initial illness, as recrudescences of the original infection to be distinguished from true second attacks due to reinfection, which were distinctly rare. Still found that between *four months* and two years after the first attack there was an interval during which *second attacks had never been recorded*, and he therefore postulated about two years as the probable *maximum duration of the immunity* resulting from an acute attack. Of the 2 cases recorded by *Colonel Lipscomb in his letter* in this issue, in one the second illness occurred about four months after the initial attack and may possibly have been a recrudescence; in the other the second attack was separated from the first by nine years and reinfection is probable. In 1938 Fischer and Stillerman[3] collected 13 authentic instances of second attacks arising two to twenty-four years after the first. They added a further 4 examples observed during the 1935 outbreak in New York. After making a statistical study of this outbreak and considering the available data they concluded that the admittedly very low rate of incidence of second attacks was not evidence that any immunity was necessarily conferred by an attack of poliomyelitis. In 1936 Wildtgrube[4] made the interesting observation that in only 1 of 13 cases recorded as having two separate attacks did the second paralyse muscles which had been affected in the first.

Monkeys which had recovered from one experimental infection with poliomyelitis were *shown by Flexner*[5] to

THE METRIC SYSTEM IN MEDICINE

HORACE FINNEMORE
B.Sc. Lond., F.R.I.C., Ph.C.
MERLY READER IN PHARMACY, UNIVERSITY OF SYDNEY

HERE seems to be a decided tendency to adopt the ric system in the prescribing and administration of licines, especially those recently introduced. But if metric system is to displace the well-established erial and apothecaries' systems, which are fairly sfactory, it must be simple enough to be readily lerstood by doctors, nurses, and pharmacists. The ent metric system contains some elements that mar intrinsic simplicity and may be the cause of much fusion and some accidents.

e are concerned here only with weights and volumes. *British Pharmacopœia* took an important step in its issue when it confined itself to a few units of weight volume, discarding many that were formerly in vogue, h as decigrammes and centigrammes. The official ghts and measures are now as follows:

Weight	*Volume*
Kilogram	Litre
Gramme	Millilitre or mil
Milligram	Microl (a millionth of a litre)
Microgram (a millionth of a gramme)	

This table shows first of all the effect of the divergent of the prefixes: kilo- (1000), milli- (one-thousandth), micro- (one-millionth). Since these are used to ify non-corresponding units, they result at once in a k of uniformity; for if 1000 grammes are expressed a kilogram, then the volume corresponding to that uld receive the same prefix. Similarly, if a gramme taken as the unit of weight there should be a responding volume, not with the prefix milli-, which icates that it is a thousandth part of some other it.

The difficulty can be overcome very easily. The ume formerly expressed as a cubic centimetre has been laced in the *British Pharmacopœia* by the more urate term millilitre, and for this the term "mil" been adopted for doses; we thus have already at nd a simple term that expresses accurately the volume responding to 1 gramme and for which measures are eady in use. From this we can derive a new term for thousandth part of it, the "millimil," which will resent the volume corresponding to 1 milligram. e millimil would supplant both the cubic millimetre mm.), sometimes used in scientific papers, and the rol or microlitre, a millionth part of a litre. The ger of confusion between microl and microgram uld thus be avoided. The table of weights and asures and their abbreviations would then be:

Weight	*Volume*
Kilogram (kg.)	Kilomil (kml.)
Gramme (g.)	Mil (ml.)
Milligram (mg.)	Millimil (mml. or mlm.)
Microgram (µg.)	Micromil (µml.)

For practical purposes the gramme and milligram l the mil and millimil are alone required for doses, d the restriction to two units which differ a thousandl from each other would be a valuable safeguard inst their confusion. There is a slight discordance the use of the abbreviation mlm. for millimil. By alogy with mg. for milligram mml. might be pretable, but when mml. is written it might be confused ith mil or ml. However, since the mlm. or mml. is ly a thousandth part of a mil there need be no anxiety out their doses being confused.

RULES FOR PRESCRIBING

In prescribing in the metric system two simple rules should be observed:

(1) All preparations for internal administration should be written for the single dose, whether for pills, tablets, mixtures, or linctuses, the number of doses then being stated. (This is nearly always done now.)

(2) Preparations for external use should be prescribed in 10 mil or 10 gramme units in the case of eye-ointments, &c., which are required in very small quantities; but in all other cases the units should be 100 grammes or mils. (This is to reduce the chance of arithmetical error.)

Liquid preparations for internal administration should be adjusted in volume to correspond to the domestic measures still used for administering them. These are:

Teaspoon,	corresponding to	4 mils
Dessertspoon,	,,	8 mils
Tablespoon,	,,	16 mils

These volumes are approximate only, but it is merely the volume of the vehicle that is affected.

An important requirement is that a ten-dose system should be adopted in prescribing bottles of medicine. Twenty doses would represent a week's supply, and fifteen doses for five days would be admissible. There is no point in using the metric system if we retain the present sixteen-dose bottle.

Before the suggested simplified metric system was fully adopted, there might be a stage when it would be desirable to be able to think in the two systems. To convert imperial into metric weights the simple factors provided for prescribers by the *British Pharmacopœia* could then be used:

$$\text{To convert}\left\{\begin{matrix}\text{grains}\\ \text{or}\\ \text{minims}\end{matrix}\right\}\text{ to }\left\{\begin{matrix}\text{grammes}\\ \text{or}\\ \text{mils}\end{matrix}\right\}\text{ divide by 15}$$

$$\text{To convert}\left\{\begin{matrix}\text{grains}\\ \text{or}\\ \text{minims}\end{matrix}\right\}\text{ to }\left\{\begin{matrix}\text{milligrams}\\ \text{or}\\ \text{millimils}\end{matrix}\right\}\text{ multiply by 60}$$

Two formulæ will make this clear:

Diamorphine hydrochloride ..	gr.	$^1/_{12}$	×	60	=	5 mg.
Tincture of belladonna ..	min.	5	×	60	=	300 mml.
Oxymel of squill	min.	30	÷	15	=	2 mils
Spirit of chloroform	min.	3	×	60	=	180 mml.
Water to	min.	60	÷	15	=	4 mils

The linctus, send 10 doses. One teaspoonful at bedtime.

Sodium bicarbonate	gr.	10	×	60	=	600 mg.
Oil of peppermint	min.	$^1/_2$	×	60	=	30 mml.
Spirit of chloroform	min.	5	×	60	=	300 mml.
Comp. infusion of gentian to	min.	240	÷	15	=	16 mils

The mixture, send 10 doses. One tablespoonful for a dose.

If quantities less than 1 gramme or 1 mil are written in milligrams and millimils there is the added advantage that decimal points are not used.

Bottles of suitable size for these liquids to be dispensed would soon be provided when required.

SUPERANNUATION IN THE NATIONAL HEALTH SERVICE

THE regulations affecting pensions for practitioners under the National Health Service have now been issued in a booklet of 88 pages,[1] with an explanatory circular (148/47). It is impossible in a short article to give anything like a complete synopsis of the regulations, but the broad principles of the scheme are as follows:

The scheme is designed to provide benefits comparable with those of an established civil servant under the Superannuation Acts, 1918–46. The main benefits are threefold: (*a*) a pension on retirement; (*b*) a retiring allowance on retirement; and (*c*) a widow's pension if left subclavian artery gave place to an almost inert descending aorta. This latter was not unduly diminished in size as it is if a hypoplastic condition is encountered. Division of the mediastinal pleura simplified the recognition of the structures, but before adequate mobilisation could be obtained the upper two intercostal arteries on the left and one on the right had to be divided between ligatures. A bronchial artery and the ligamentum arteriosum at the level of the coarctation were also severed. Once the whole area had been suitably freed occluding clamps were placed on the aorta above and well below the coarctation and also on the subclavian artery. The stricture was then excised and the open ends of the aorta brought together. Restoration of continuity was established by using a fine continuous silk suture which was very accurately placed so that eversion of the ends was obtained. In this respect the junction differs from that practised by Crafoord, who aims to avoid puncturing the intima. Before releasing the clamps the patient's head was well lowered and blood-transfusion (using two veins) hastened. The chest was closed in the usual way in layers with aspiration of all air to ensure expansion of the lung. In less than three weeks the patient was shown again with the records of the blood-pressure in the upper and lower limbs approximating to normal.

The pioneer work on congenital anomalies of the heart done by Dr. Blalock and his colleagues should not be allowed to overshadow his other contributions to surgery. The treatment of myasthenia gravis and constrictive pericarditis owe much to his original work and publications, and his observations on shock are probably even more important.

PATENTS FOR MEDICINE OR FOOD

MEDICINE and food take up very few paragraphs in the final report of the Swan Committee set up by the Board of Trade to suggest improvements in the Patents and Designs Acts.[1] Patent law is notoriously technical and the committee had naturally to consider many other aspects both of practice and of general policy—such, for instance, as the alleged unfairness to an employee inventor, who, when he has successfully exercised his inventive skill, is said to see all the profit pocketed by his employer.

The main concern of medicine is with section 38A of the principal Act. This section begins by barring the right to claim protection for substances "produced by chemical processes or intended for food or medicine." Claims are allowable only when limited to particular processes of manufacture—a restriction which was inserted in our law in 1919 at a time when this country had become aware that the previous law had been dangerously tolerant towards the monopolistic ingenuity of the German dyestuffs industry. Food and medicine, being thus linked almost accidentally with "chemical processes" for better or for worse, continue (as the committee's final report shows) to be treated in the light of that association rather than upon their own merits. The words "chemical processes" are, to begin with, awkward to define. The law forbids claims on behalf of substances (other than food and medicine) only when they are made by "chemical processes"; if made by physical processes, they are patentable. The committee were pressed with arguments that this limitation on claims for new substances was not in accord with modern scientific development in an age of nuclear physics and chemistry. The real invention lies in the discovery of something which has novel and useful properties; the process of manufacture may involve little novelty in itself. These arguments prevailed. The committee recommend that the limitation be repealed. They consider too that the claim for a new substance should always be deemed to exclude the same substance when found in nature.

Having definitely favoured the removal of the existing *limitation on claims for new substances produced by* "chemical processes," the committee go on to observe that the arguments for removal do not apply with the same force to substances intended for food or medicine. They confess that, in so far as the section deals with food and medicine, they would have been inclined to leave the law as it stands. But they were pressed with the fact that a new chemical substance may be capable of use both for industrial purposes and for food or medicine. Were such substances to claim protection without limitation in regard to manufacturing process, [illegible] were they to be regarded as food or medicine only to be protected in relation to a particular process of manufacture ? In other words, was the existing limitation [illegible] be retained on claims for chemical substances as well [illegible] on claims for substances used for medicine or food, [illegible] was the limitation to be cancelled alike for all [illegible] chemical substances whether used for industrial purposes or for food or medicine ? The committee ended the dilemma by deciding in favour of equality: they propose to cancel the limitation in both classes of case.

Under subsection (2) of the existing section 38A the Comptroller of Patents must, unless he sees good reason to the contrary, grant any applicant a licence limited to the use of the invention for the purposes of the preparation or production of food or medicine but not otherwise. In its second interim report[2] the committee wanted to see this subsection repealed. In view of their recent conclusions set out above, they now want the subsection retained after all. One other recommendation concerns substances intended for medicine or food. The present law contains a proviso which prevents claims for the protection of "admixtures" of such substances. The committee think this proviso should be extended to prevent claims on behalf of mere admixtures resulting only in the aggregation of the known properties of the ingredients of the substance.

Readers primarily interested in medical research and discovery will hope that, if the committee's proposals take shape in a Bill brought before Parliament, the drafting of these complicated matters will be as simple as possible. Is it too much to hope that the provisions respecting substances intended for use as medicine will be dealt with in a separate clause and on their own merits ?

AN ANEURYSMAL RECORD

THE average duration of life from the onset of symptoms in 482 cases of saccular aneurysm of the thoracic aorta in men was nineteen months, according to [illegible] follow-up by Colt.[3] But in clinical medicine averages may be misleading. In a case of aneurysm of the thoracic aorta recorded by Kauntze[4] the man was first seen *at the age of 36, in 1921, on account* of dysphagia and hæmoptysis. Radiograms showed the presence of [illegible] saccular aneurysm of the thoracic aorta. There was also a history of pain in the back of the head and in the left side of the neck. In 1933 the patient was successfully operated on for acute appendicitis; in 1934 he had jaundice; in 1941 there was a recurrence of the hæmoptysis; and in 1944 he suddenly became aphasic. In 1946 he was complaining of weakness of the right arm, but his general condition was "reasonably good," there was no dysphagia, and his occipital and neck pain had disappeared. No antisyphilitic treatment was given after 1940 when the blood Wassermann reaction was negative and the Kahn reaction positive. Before that, treatment had consisted mainly of bismuth injections and mercury by mouth at intervals. If the patient's original symptoms can be attributed to the aneurysm, as seems highly likely, it has already existed for at least 27 years.

Public Health

CHILDHOOD ADVISORY CLINICS IN CAMBERWELL

ALEX COMFORT
M.B. Camb., D.C.H.
EDICAL OFFICER, TODDLER'S CLINICS, BOROUGH OF CAMBERWELL

NICS for the advisory care of children aged 2–5 were instituted in Camberwell, shortly before the bridging the gap between the infant-welfare and l medical services. The war closed all these clinics, ildren were dispersed, and in 1946 it was necessary gin again from scratch.

response of parents to such a service proved the which it fulfils, and it seems reasonable to expect a wider and more integrated public-health service nake such clinics general throughout the country. work done in them should be described for criticism pediatricians, administrators, and the general itioners with whom clinics must cooperate.

METHOD

e clinics were held, with one weekly session each. public health authority possesses, through its health- r service, a fairly complete list of the child popula- supplemented by the infant-welfare records.

invitation signed by the M.O.H. was sent to the ts of every child in the age-group, initially to a m comprising older children returned from evacua- who had not been supervised by the infant-welfare es in the borough, and later, when a weekly attend- was being secured, to each parent on the child's day, the dates being selected monthly to cover the e eligible child population. This method led to an dance which varied from district to district, seldom ding 50%. The invitations were followed by nal calls from health visitors, who gave explanations discussed individual problems. The percentage idance depended most on this follow-up in the omically poorer zones, and results in general d a good deal with the personality of the health or and the previous success of infant-welfare clinics, he most important single factor in securing coöpera- from parents was undoubtedly the propaganda ucted by the mothers who had attended and ved advice.

History

proved simplest, both from the statistical and the medical point, to base the examination on a set questionnaire. child at its first visit was weighed and measured, and ory was taken to cover the following points:

Personal and family health record.

Immunisation and vaccination.

Natal data: labour and neonatal, birth-weight, breast- g and artificial feeding.

Ear, nose, and throat: colds, snoring, mouth-breathing, , earache, otorrhœa, cough.

Eyesight, headache, strabismus.

Appetite and bowel habit.

Landmarks: walking, talking; left-handedness.

Sleep, pavor nocturnus, enuresis

Dental: teething time and dental status.

he same questions were put to each parent in about the form and order, concluding with "Any pains anywhere?" "Any worries about the child?"—two blunderbuss tions which evoked the greatest number of missed points. individual history had to be condensed into a routine ry about acute infections and "any other illnesses or ations." Such relevant points as attacks of nephritis e often volunteered only after pressure, and we soon t to repeat the question, once from the health visitor at the reception desk and once from the doctor examining. Family history was covered (not always adequately) by asking "Has anyone on either side of the family had rheumatism, fits, tuberculosis, asthma, or hay-fever?"—another wide net, which was reached empirically and modified in the asking to the apparent intelligence of the attending parent.

This crude method of history-taking justified itself in dealing with large numbers of predominantly healthy children. Most parents who forgot important facts at the first asking produced them later in the examination.

Physical examination

Besides being weighed and measured, every child was examined for pediculi, postural defects, adenitis, and dental caries. Heart and chest were auscultated; tonsils, teeth, and prepuce were examined; and ears were scrutinised externally, otoscopy being kept, on a basis of experience, for those who had any obscure complaint or a history of recent whooping-cough, tonsillitis, or earache.

Here again the examination was stereotyped at a level of completeness which seemed to us sufficient for the purposes of the clinics, and supplemented on the history. In view of our terms of reference, extra time was better spent on advice and discussion with the parent and in giving health instruction than on physical examination in detail.

One of the chief problems for doctors with little experience in pædiatrics, the class most likely to find themselves doing this work, is to strike a balance between examination and advice in the time available. The routine described here covered all the data required in deciding what to do next. The function of the clinic as a clearing-house, not a thera- peutic centre competing in the normal treatment facilities, had to be kept constantly in mind.

Vollmer tests

Beside this examination, every child was patch-tested for tuberculin-sensitivity by the Vollmer-Goldberg test, and the routine ward tests of urine were noted on the card.

The limitations of this test were fully recognised, but it is not feasible to undertake Mantoux tests involving injection in clinics such as these. The weight of immunisation, vaccina- tion, cod-liver oil, orange-juice, and minor surgery lies heavy upon the attending parent. The test was refused by less than six patients in a year.

In our clinics acetone was used as a cleaning agent, and the patch affixed on the back, where the child could not get at it, with the set formula: "This is a tuberculin test. Don't be scared if it is positive—it doesn't mean that your child will be ill. The test tells us when he first meets tubercle germs, so that we can see that they do not hurt him. Do not get it wet. Take it off the day after tomorrow and bring the child, not the patch, today week." The content of this admonition is an important factor both in the success of the test and in the repute of the clinic in the neighbourhood. When the purpose behind it is explained, with the comment that it is not a form of immunisation, many uninvited parents request a patch-test for the whole family.

We were, and remain, in doubt about the prognostic attitude to take in explaining positive Vollmer tests to the parent. In interpreting negative results we found that the manu- facturers' date-limit was not reliable under our conditions of storage, as exemplified by the falling off of positive readings toward the end of each box. The effective life of a box of patches was finally taken to be about two months. With improved storage this might well be lengthened, but the retention of boxes in stock for a longer time proved too risky.

The age-group at risk was that in which tonsillar and dental defects, rickets, infantile tuberculosis, mild and hence missed mental defect, congenital heart malforma- tions, and acute infections might be expected; so special precautions were directed to all these. The state of wait- ing-lists in nearby hospitals exerted a beneficial influence in sharpening the criteria for advising tonsillectomy and other forms of surgical treatment. No medicines other than supplements and occasionally oxyuricides were given at the clinics; detected defects were always referred elsewhere.

Disposal of Cases

All Vollmer-positives were referred direct to the tuberculosis officer at a special session designed to prevent contact with known cases. The poor prognosis in some

the doctor's wife survives him. If a male doctor is unmarried he will receive a retiring allowance three times the value of that granted in the case of a married practitioner. The scheme is a contributory one, and a practitioner will have to pay in 6% of his or her remuneration, the executive council contributing 8% of his remuneration. The rate of remuneration is, of course, not yet calculable as the conditions have not yet been agreed with the profession. For the purpose of this note, however, "remuneration" means all payments made to *the practitioner in respect of general medical services* provided by him, less a sum for practice expenses, in accordance with a formula laid down by the Minister, and less the remuneration approved by the Minister of any assistant practitioner in his employment. If the practitioner is a partner, and particulars of the partnership agreement are disclosed to the executive council, then his share of the total remuneration of the partnership is equivalent to his share of the partnership profits.

Pensions

The pension to be paid to a practitioner will be on the following scale: (*a*) in respect of each year of contributing service as a practitioner, $1\frac{1}{2}$% of his remuneration for that year; (*b*) in respect of each year of contributing service otherwise than as a practitioner 1/80th of his average remuneration at the date on which he last ceased to be employed in such other capacity; and (*c*) in respect of each year of non-contributing service 1/160th of his average remuneration at the date on which he last ceased to be employed in such other capacity. If the contributing service of a practitioner exceeds forty years and he has no service in any other capacity the pension will be calculated by reference to the last forty years of such contributing service.

Retiring Allowance

The retiring allowance to be paid to a practitioner will be the aggregate of the following amounts: (*a*) in respect of each year of contributing service as a practitioner $4\frac{1}{2}$% of his remuneration for that year; (*b*) in respect of each year of contributing service otherwise than as a practitioner 3/80ths, and in respect of each year of non-contributing service 3/160ths, in both cases of his average remuneration at the date on which he last ceased to be employed in such other capacity; but in the case of a married male practitioner in respect of whose service a widow's pension may become payable the amount of the retiring allowance will be reduced to 1/3rd.

Widow's Pension

The widow's pension is equivalent to a third of the pension payable to the practitioner or of the amount of pension to which he would have been entitled had he retired on the day preceding his death. It must also be noted, however, that her pension will be reduced or raised according to whether her age was less or greater than that of her husband. It will cease if she remarries.

Qualification for Pension

A doctor will be entitled to his annual pension if he (i) has completed ten years' service and is incapable of discharging his duties through ill health; (ii) has attained the age of sixty and completed ten years' service. He will be entitled to the retiring allowance if he satisfies the conditions in (i) above, or has attained the age of sixty and has completed five years' service.

Death Gratuity

If a practitioner (*a*) dies and at the date of his death had completed five years' service; or (*b*) ceases to be a practitioner after completing five years' service and dies within twelve months after so ceasing, without having received a return of contributions or become entitled to any other benefit under the regulations, and without having again become entitled to participate in superannuation benefits, or (*c*) if he dies after having become entitled to a pension or retiring or injury allowance or short-service gratuity, then the Minister will, subject to certain exceptions, pay a death gratuity of a sum equal to (i) $4\frac{1}{2}$% of his remuneration for each year of contributing service as a practitioner or, widow's pension is payable, $1\frac{1}{2}$% thereof; (ii) in of each year of contributing service otherwise th a practitioner 3/80ths of his average remunerati there is a widow 1/80th) at the date on which he ceased to be employed otherwise than as a practitioner; and (iii) subject to the same conditions 3/160ths of average remuneration in respect of each year of no contributing service.

Short-service Gratuity

A practitioner who has completed more than five less than ten years' service, and who ceases to through incapacity to discharge efficiently the his employment by reason of permanent ill infirmity of mind or body, shall, unless he is to a retiring allowance, be entitled to a short gratuity equal to the amount of his average remuneration. There is also provision for an allowance. A practitioner is permitted to of his or her pension or injury allowance to a or dependant. This will permit women doctors to provision if necessary for their husbands.

Return of Contributions

Contributions with interest may be returned in cert cases, as when a practitioner ceasing to be employ is not entitled to a pension or retiring or injury allowa or a short-service gratuity. In case of death, if death gratuity is payable, the legal personal represen tives will be entitled to receive the amount of doctor's contributions with compound interest at $2\frac{1}{2}$ per annum with half-yearly rests.

Life-assurance Policies

Any doctor holding a life-assurance policy may tract out of the scheme by applying to the council within three months after the appointed He will then receive 8% of his remuneration contribution towards his premiums.

Reduction of Pension

The Minister may, subject to medical eviden require a person on incapacity pension or injury allowa to return to employment in the scheme—possibly o part-time employment with a consequent reduction suspension of the allowance. There is also provision a reduction of a pension on the lines of the local gove ment superannuation scheme where a pensioner ta on further employment remunerated from public fun

Service with the Forces, &c.

Provision is made for continuation in the sche during service with the Armed Forces, but this seems be prospective, not retrospective.

Service in various forms of employment will be coun towards superannuation benefits. Contributing serv covers service in respect of which the practitioner h made the contributions required by the regulations p previous employment if falling within certain definitio It does not appear, however, that service as a Natio Health Insurance practitioner can be aggregated. No contributory service is defined in the regulations follows: There shall be reckonable as non-contributor service in relation to the employment of an officer b an employing authority any service which is not reck able as contributing service and which is not reckona solely for the purpose of determining whether benefit is payable under the regulations. This somewh involved section will doubtless be clarified later.

The scheme will be administered by a Health Ser Superannuation Division of the Ministry of Health, 28, Princes Gate, London, S.W.7. It will be by contributions from the participants in its benefits by contributions from the Exchequer. It will not funded but will be subjected to actuarial invest periodically at seven-year intervals.

CHILDHOOD ADVISORY CLINICS IN CAMBERWELL

ALEX COMFORT
M.B. Camb., D.C.H.
MEDICAL OFFICER, TODDLER'S CLINICS, BOROUGH OF CAMBERWELL

LINICS for the advisory care of children aged 2–5 rs were instituted in Camberwell, shortly before the bridging the gap between the infant-welfare and ool medical services. The war closed all these clinics, children were dispersed, and in 1946 it was necessary begin again from scratch.

The response of parents to such a service proved the d which it fulfils, and it seems reasonable to expect a wider and more integrated public-health service make such clinics general throughout the country. e work done in them should be described for criticism pædiatricians, administrators, and the general ctitioners with whom clinics must cooperate.

METHOD

ive clinics were held, with one weekly session each. e public health authority possesses, through its health-itor service, a fairly complete list of the child popula-n, supplemented by the infant-welfare records.

An invitation signed by the M.O.H. was sent to the ts of every child in the age-group, initially to a on comprising older children returned from evacua- who had not been supervised by the *infant-welfare* vices in the borough, and later, when a weekly attend-ce was being secured, to each parent on the child's thday, the dates being selected monthly to cover the tire eligible child population. This method led to an endance which varied from district to district, seldom ceeding 50%. The invitations were followed by rsonal calls from health visitors, who gave explanations d discussed individual problems. The percentage endance depended most on this follow-up in the nomically poorer zones, and results in general ned a good deal with the personality of the health itor and the previous success of infant-welfare clinics, t the most important single factor in securing coöpera-n from parents was undoubtedly the propaganda nducted by the mothers who had attended and ceived advice.

e history

It proved simplest, both from the statistical and the medical wpoint, to base the examination on a set questionnaire. ch child at its first visit was weighed and measured, and istory was taken to cover the following points :

1) Personal and family health record.
2) Immunisation and vaccination.
3) Natal data: labour and neonatal, birth-weight, breast-ding and artificial feeding.
4) Ear, nose, and throat: colds, snoring, mouth-breathing, ss, earache, otorrhœa, cough.
5) Eyesight, headache, strabismus.
6) Appetite and bowel habit.
7) Landmarks: walking, talking; left-handedness.
8) Sleep, pavor nocturnus, enuresis.
9) Dental: teething time and dental status.

The same questions were put to each parent in about the me form and order, concluding with "Any pains anywhere?" d "Any worries about the child?"—two blunderbuss estions which evoked the greatest number of missed points. e individual history had to be condensed into a routine quiry about acute infections and "any other illnesses or erations." Such relevant points as attacks of nephritis re often volunteered only after pressure, and we soon arnt to repeat the question, once from the health visitor at the reception desk and once from the doctor examining. Family history was covered (not always adequately) by asking "Has anyone on either side of the family had rheumatism, fits, tuberculosis, asthma, or hay-fever?"—another wide net, which was reached empirically and modified in the asking to the apparent intelligence of the attending parent.

This crude method of history-taking justified itself in dealing with large numbers of predominantly healthy children. Most parents who forgot important facts at the first asking produced them later in the examination.

Physical examination

Besides being weighed and measured, every child was examined for pediculi, postural defects, adenitis, and dental caries. Heart and chest were auscultated; tonsils, teeth, and prepuce were examined; and ears were scrutinised externally, otoscopy being kept, on a basis of experience, for those who had any obscure complaint or a history of recent whooping-cough, tonsillitis, or earache.

Here again the examination was stereotyped at a level of completeness which seemed to us sufficient for the purposes of the clinics, and supplemented on the history. In view of our terms of reference, extra time was better spent on advice and discussion with the parent and in giving health instruction than on physical examination in detail.

One of the chief problems for doctors with little experience in pædiatrics, the class most likely to find themselves doing this work, is to strike a balance between examination and advice in the time available. The routine described here covered all the data required in deciding what to do next. The function of the clinic as a clearing-house, not a therapeutic centre competing in the normal treatment facilities, had to be kept constantly in mind.

Vollmer tests

Beside this examination, every child was patch-tested for tuberculin-sensitivity by the Vollmer-Goldberg test, and the routine ward tests of urine were noted on the card.

The limitations of this test were fully recognised, but it is not feasible to undertake Mantoux tests involving injection in clinics such as these. The weight of immunisation, vaccination, cod-liver oil, orange-juice, and minor surgery lies heavy upon the attending parent. The test was refused by less than six patients in a year.

In our clinics acetone was used as a cleaning agent, and the patch affixed on the back, where the child could not get at it, with the set formula: "*This is a tuberculin test. Don't be scared if it is positive—it doesn't mean that your child will be ill. The test tells us when he first meets tubercle germs, so that we can see that they do not hurt him. Do not get it wet. Take it off the day after tomorrow and bring the child, not the patch, today week.*" The content of this admonition is an important factor both in the success of the test and in the repute of the clinic in the neighbourhood. When the purpose behind it is explained, with the comment that it is not a form of immunisation, many uninvited parents request a patch-test for the whole family.

We were, and remain, in doubt about the prognostic attitude to take in explaining positive Vollmer tests to the parent. In interpreting negative results we found that the manufacturers' date-limit was not reliable under our conditions of storage, as exemplified by the falling off of positive readings toward the end of each box. The effective life of a box of patches was finally taken to be about two months. With improved storage this might well be lengthened, but the retention of boxes in stock for a longer time proved too risky.

The age-group at risk was that in which tonsillar and dental defects, rickets, infantile tuberculosis, mild and hence missed mental defect, congenital heart malformations, and acute infections might be expected; so special precautions were directed to all these. The state of waiting-lists in nearby hospitals exerted a beneficial influence in sharpening the criteria for advising tonsillectomy and other forms of surgical treatment. No medicines other than supplements and occasionally oxyuricides were given at the clinics; detected defects were always referred elsewhere.

Disposal of Cases

All Vollmer-positives were referred direct to the tuberculosis officer at a special session designed to prevent contact with known cases. The poor prognosis in some

the doctor's wife survives him. If a male doctor is unmarried he will receive a retiring allowance three times the value of that granted in the case of a married practitioner. The scheme is a contributory one, and a practitioner will have to pay in 6% of his or her remuneration, the executive council contributing 8% of his remuneration. The rate of remuneration is, of course, not yet calculable as the conditions have not yet been agreed with the profession. For the purpose of this note, however, "remuneration" means all payments made to the practitioner in respect of general medical services provided by him, less a sum for practice expenses, in accordance with a formula laid down by the Minister, and less the remuneration approved by the Minister of any assistant practitioner in his employment. If the practitioner is a partner, and particulars of the partnership agreement are disclosed to the executive council, then his share of the total remuneration of the partnership is equivalent to his share of the partnership profits.

Pensions

The pension to be paid to a practitioner will be on the following scale: (*a*) in respect of each year of contributing service as a practitioner, $1^1/_2$% of his remuneration for that year; (*b*) in respect of each year of contributing service otherwise than as a practitioner 1/80th of his average remuneration at the date on which he last ceased to be employed in such other capacity; and (*c*) in respect of each year of *non-contributing* service 1/160th of his average remuneration at the date on which he last ceased to be employed in such other capacity. If the contributing service of a practitioner exceeds forty years and he has no service in any other capacity the pension will be calculated by reference to the last forty years of such contributing service.

Retiring Allowance

The retiring allowance to be paid to a practitioner will be the aggregate of the following amounts: (*a*) in respect of each year of contributing service as a practitioner $4^1/_2$% of his remuneration for that year; (*b*) in respect of each year of contributing service otherwise than as a practitioner 3/80ths, and in respect of each year of non-contributing service 3/160ths, in both cases of his average remuneration at the date on which he last ceased to be employed in such other capacity; but in the case of a married male practitioner in respect of whose service a widow's pension may become payable the amount of the retiring allowance will be reduced to 1/3rd.

Widow's Pension

The widow's pension is equivalent to a third of the pension payable to the practitioner or of the amount of pension to which he would have been entitled had he retired on the day preceding his death. It must also be noted, however, that her pension will be reduced or raised according to whether her age was less or greater than that of her husband. It will cease if she remarries.

Qualification for Pension

A doctor will be entitled to his annual pension if he (i) has completed ten years' service and is incapable of discharging his duties through ill health; (ii) has attained the age of sixty and completed ten years' service. He will be entitled to the retiring allowance if he satisfies the conditions in (i) above, or has attained the age of sixty and has completed five years' service.

Death Gratuity

If a practitioner (*a*) dies and at the date of his death had completed five years' service; or (*b*) ceases to be a practitioner after completing five years' service and dies within twelve months after so ceasing, without having received a return of contributions or become entitled to any other benefit under the regulations, and without having again become entitled to participate in superannuation benefits, or (*c*) if he dies after having become entitled to a pension or retiring or injury allowance or short-service gratuity, then the Minister will, subject to certain exceptions, pay a death gratuity of a sum equal to (i) $4^1/_2$% of his remuneration for each year of contributing service as a practitioner or, if widow's pension is payable, $1^1/_2$% thereof; (ii) in of each year of contributing service otherwise than a practitioner 3/80ths of his average remuneration there is a widow 1/80th) at the date on which he ceased to be employed otherwise than as a practitioner and (iii) subject to the same conditions 3/160ths of average remuneration in respect of each year of no contributing service.

Short-service Gratuity

A practitioner who has completed more than five less than ten years' service, and who ceases to be employ through incapacity to discharge efficiently the duti his employment by reason of permanent ill health infirmity of mind or body, shall, unless he is enti to a retiring allowance, be entitled to a short-ser gratuity equal to the amount of his average remuneration. There is also provision for an allowance. A practitioner is permitted to allocate of his or her pension or injury allowance to a s or dependant. This will permit women doctors to provision if necessary for their husbands.

Return of Contributions

Contributions with interest may be returned in cert cases, as when a practitioner ceasing to be employ is not entitled to a pension or retiring or injury allowa or a short-service gratuity. In case of death, if death gratuity is payable, the legal personal represen tives will be entitled to receive the amount of doctor's contributions with compound interest at $2^1/_2$ per annum with half-yearly rests.

Life-assurance Policies

Any doctor holding a life-assurance policy may tract out of the scheme by applying to the execu council within three months after the appointed He will then receive 8% of his remuneration contribution towards his premiums.

Reduction of Pension

The Minister may, subject to medical eviden require a person on incapacity pension or injury allowa to return to employment in the scheme—possibly part-time employment with a consequent reduction suspension of the allowance. There is also provision a reduction of a pension on the lines of the local gover ment superannuation scheme where a pensioner tak on further employment remunerated from public fun

Service with the Forces, &c.

Provision is made for continuation in the sche during service with the Armed Forces, but this seems be prospective, not retrospective.

Service in various forms of employment will be count towards superannuation benefits. Contributing serv covers service in respect of which the practitioner h made the contributions required by the regulations pl previous employment if falling within certain definitio It does not appear, however, that service as a Natio Health Insurance practitioner can be aggregated. No contributory service is defined in the regulations follows: There shall be reckonable as non-contributo service in relation to the employment of an officer b an employing authority any service which is not reck able as contributing service and which is not reckona solely for the purpose of determining whether benefit is payable under the regulations. This somewh involved section will doubtless be clarified later.

The scheme will be administered by a Health Servic Superannuation Division of the Ministry of Health, 28, Princes Gate, London, S.W.7. It will be financ by contributions from the participants in its benefits by contributions from the Exchequer. It will not funded but will be subjected to actuarial investigati periodically at seven-year intervals.

he response of parents to such a service proved the l which it fulfils, and it seems reasonable to expect a wider and more integrated public-health service make such clinics general throughout the country. work done in them should be described for criticism pediatricians, administrators, and the general titioners with whom clinics must coöperate.

METHOD

ive clinics were held, with one weekly session each. public health authority possesses, through its health-tor service, a fairly complete list of the child popula-, supplemented by the infant-welfare records.

n invitation signed by the M.O.H. was sent to the nts of every child in the age-group, initially to a on comprising older children returned from evacua- who had not been supervised by the infant-welfare res in the borough, and later, when a weekly attend- e was being secured, to each parent on the child's thday, the dates being selected monthly to cover the ire eligible child population. This method led to an ndance which varied from district to district, seldom eeding 50%. The invitations were followed by sonal calls from health visitors, who gave explanations d discussed individual problems. The percentage endance depended most on this follow-up in the nomically poorer zones, and results in general ed a good deal with the personality of the health tor and the previous success of infant-welfare clinics, t the most important single factor in securing coöpera- n from parents was undoubtedly the propaganda ducted by the mothers who had attended and eived advice.

e History

It proved simplest, both from the statistical and the medical point, to base the examination on a set questionnaire. ch child at its first visit was weighed and measured, and tory was taken to cover the following points:

1) Personal and family health record.
2) Immunisation and vaccination.
3) Natal data: labour and neonatal, birth weight, breast- and artificial feeding.
4) Ear, nose, and throat: colds, snoring, mouth-breathing, , earache, otorrhœa, cough.
5 Eyesight, headache, strabismus.
6) Appetite and bowel habit.
7) Landmarks: walking, talking; left-handedness.
) Sleep, pavor nocturnus, enuresis.
9) Dental: teething time and dental status.

he same questions were put to each parent in about the e form and order, concluding with "Any pains anywhere?" d "Any worries about the child?"—two blunderbuss tions which evoked the greatest number of missed points. s individual history had to be condensed into a routine uiry about acute infections and "any other illnesses or rations." Such relevant points as attacks of nephritis e often volunteered only after pressure, and we soon nt to repeat the question, once from the health visitor at the reception desk and once from the doctor examining. Family history was covered (not always adequately) by asking "Has anyone on either side of the family had rheumatism, fits, tuberculosis, asthma, or hay-fever?"—another wide net, which was reached empirically and modified in the asking to the apparent intelligence of the attending parent.

This crude method of history-taking justified itself in dealing with large numbers of predominantly healthy children. Most parents who forgot important facts at the first asking produced them later in the examination.

Physical examination

Besides being weighed and measured, every child was examined for pediculi, postural defects, adenitis, and dental caries. Heart and chest were auscultated; tonsils, teeth, and prepuce were examined; and ears were scrutinised externally, otoscopy being kept, on a basis of experience, for those who had any obscure complaint or a history of recent whooping-cough, tonsillitis, or earache.

Here again the examination was stereotyped at a level of completeness which seemed to us sufficient for the purposes of the clinics, and supplemented on the history. In view of our terms of reference, extra time was better spent on advice and discussion with the parent and in giving health instruction than on physical examination in detail.

One of the chief problems for doctors with little experience in pædiatrics, the class most likely to find themselves doing this work, is to strike a balance between examination and advice in the time available. The routine described here covered all the data required in deciding what to do next. The function of the clinic as a clearing-house, not a therapeutic centre competing in the normal treatment facilities, had to be kept constantly in mind.

Vollmer tests

Beside this examination, every child was patch-tested for tuberculin-sensitivity by the Vollmer-Goldberg test, and the routine ward tests of urine were noted on the card.

The limitations of this test were fully recognised, but it is not feasible to undertake Mantoux tests involving injection in clinics such as these. The weight of immunisation, vaccination, cod-liver oil, orange-juice, and minor surgery lies heavy upon the attending parent. The test was refused by less than six patients in a year.

In our clinics acetone was used as a cleaning agent, and the patch affixed on the back, where the child could not get at it, with the set formula: "This is a tuberculin test. Don't be scared if it is positive—it doesn't mean that your child will be ill. The test tells us when he first meets tubercle germs, so that we can see that they do not hurt him. Do not get it wet. Take it off the day after tomorrow and bring the child, not the patch, today week." The content of this admonition is an important factor both in the success of the test and in the repute of the clinic in the neighbourhood. When the purpose behind it is explained, with the comment that it is not a form of immunisation, many uninvited parents request a patch-test for the whole family.

We were, and remain, in doubt about the prognostic attitude to take in explaining positive Vollmer tests to the parent. In interpreting negative results we found that the manufacturers' date-limit was not reliable under our conditions of storage, as exemplified by the falling off of positive readings toward the end of each box. The effective life of a box of patches was finally taken to be about two months. With improved storage this might well be lengthened, but the retention of boxes in stock for a longer time proved too risky.

The age-group at risk was that in which tonsillar and dental defects, rickets, infantile tuberculosis, mild and hence missed mental defect, congenital heart malformations, and acute infections might be expected; so special precautions were directed to all these. The state of waiting-lists in nearby hospitals exerted a beneficial influence in sharpening the criteria for advising tonsillectomy and other forms of surgical treatment. No medicines other than supplements and occasionally oxyuricides were given at the clinics; detected defects were always referred elsewhere.

Disposal of Cases

All Vollmer-positives were referred direct to the tuberculosis officer at a special session designed to prevent contact with known cases. The poor prognosis in some

the doctor's wife survives him. If a male doctor is unmarried he will receive a retiring allowance three times the value of that granted in the case of a married practitioner. The scheme is a contributory one, and a practitioner will have to pay in 6 % of his or her remuneration, the executive council contributing 8 % of his remuneration. The rate of remuneration is, of course, not yet calculable as the conditions have not yet been agreed with the profession. For the purpose of this note, however, "remuneration" means all payments made to the practitioner in respect of general medical services provided by him, less a sum for practice expenses, in accordance with a formula laid down by the Minister, and less the remuneration approved by the Minister of any assistant practitioner in his employment. If the practitioner is a partner, and particulars of the partnership agreement are disclosed to the executive council, then his share of the total remuneration of the partnership is equivalent to his share of the partnership profits.

Pensions

The pension to be paid to a practitioner will be on the following scale: (*a*) in respect of each year of contributing service as a practitioner, $1^1/_2$ % of his remuneration for that year; (*b*) in respect of each year of contributing service otherwise than as a practitioner 1/80th of his average remuneration at the date on which he last ceased to be employed in such other capacity; and (*c*) in respect of each year of non-contributing service 1/160th of his average remuneration at the date on which he last ceased to be employed in such other capacity. If the contributing service of a practitioner exceeds forty years and he has no service in any other capacity the pension will be calculated by reference to the last forty years of such contributing service.

Retiring Allowance

The retiring allowance to be paid to a practitioner will be the aggregate of the following amounts: (*a*) in respect of each year of contributing service as a practitioner $4^1/_2$ % of his remuneration for that year; (*b*) in respect of each year of contributing service otherwise than as a practitioner 3/80ths, and in respect of each year of non-contributing service 3/160ths, in both cases of his average remuneration at the date on which he last ceased to be employed in such other capacity; but in the case of a married male practitioner in respect of whose service a widow's pension may become payable the amount of the retiring allowance will be reduced to 1/3rd.

Widow's Pension

The widow's pension is equivalent to a third of the pension payable to the practitioner or of the amount of pension to which he would have been entitled had he retired on the day preceding his death. It must also be noted, however, that her pension will be reduced or raised according to whether her age was less or greater than that of her husband. It will cease if she remarries.

Qualification for Pension

A doctor will be entitled to his annual pension if he (i) has completed ten years' service and is incapable of discharging his duties through ill health; (ii) has attained the age of sixty and completed ten years' service. He will be entitled to the retiring allowance if he satisfies the conditions in (i) above, or has attained the age of sixty and has completed five years' service.

Death Gratuity

If a practitioner (*a*) dies and at the date of his death had completed five years' service; or (*b*) ceases to be a practitioner after completing five years' service and dies within twelve months after so ceasing, without having received a return of contributions or become entitled to any other benefit under the regulations, and without having again become entitled to participate in superannuation benefits, or (*c*) if he dies after having become entitled to a pension or retiring or injury allowance or short-service gratuity, then the Minister will, subject to certain exceptions, pay a death gratuity of a sum equal to (i) $4^1/_2$ % of his remuneration for each year of contributing service as a practitioner or, widow's pension is payable, $1^1/_2$ % thereof; (ii) in of each year of contributing service otherwise than a practitioner 3/80ths of his average remuneration there is a widow 1/80th) at the date on which he ceased to be employed otherwise than as a practitioner and (iii) subject to the same conditions 3/160ths of average remuneration in respect of each year of no contributing service.

Short-service Gratuity

A practitioner who has completed more than five less than ten years' service, and who ceases to be employ through incapacity to discharge efficiently the duti his employment by reason of permanent ill health infirmity of mind or body, shall, unless he is enti to a retiring allowance, be entitled to a short-se gratuity equal to the amount of his average a remuneration. There is also provision for an allowance. A practitioner is permitted to allocat of his or her pension or injury allowance to a s or dependant. This will permit women doctors to provision if necessary for their husbands.

Return of Contributions

Contributions with interest may be returned in cert cases, as when a practitioner ceasing to be employ is not entitled to a pension or retiring or injury allow or a short-service gratuity. In case of death, if death gratuity is payable, the legal personal represen tives will be entitled to receive the amount of doctor's contributions with compound interest at $2^1/$ per annum with half-yearly rests.

Life-assurance Policies

Any doctor holding a life-assurance policy may tract out of the scheme by applying to the execu council within three months after the appointed He will then receive 8 % of his remuneration contribution towards his premiums.

Reduction of Pension

The Minister may, subject to medical eviden require a person on incapacity pension or injury allowa to return to employment in the scheme—possibly o part-time employment with a consequent reduction suspension of the allowance. There is also provision a reduction of a pension on the lines of the local gove ment superannuation scheme where a pensioner ta on further employment remunerated from public fun

Service with the Forces, &c.

Provision is made for continuation in the sche during service with the Armed Forces, but this seems be prospective, not retrospective.

Service in various forms of employment will be count towards superannuation benefits. Contributing serv covers service in respect of which the practitioner made the contributions required by the regulations pl previous employment if falling within certain definitio It does not appear, however, that service as a Natio Health Insurance practitioner can be aggregated. No contributory service is defined in the regulations follows: There shall be reckonable as non-contributor service in relation to the employment of an officer an employing authority any service which is not reck able as contributing service and which is not reckona solely for the purpose of determining whether benefit is payable under the regulations. This somewh involved section will doubtless be clarified later.

The scheme will be administered by a Health Servic Superannuation Division of the Ministry of Health, 28, Princes Gate, London, S.W.7. It will be financ by contributions from the participants in its benefits by contributions from the Exchequer. It will not funded but will be subjected to actuarial investigat periodically at seven-year intervals.

CHILDHOOD ADVISORY CLINICS IN CAMBERWELL

ALEX COMFORT
M.B. Camb., D.C.H.
MEDICAL OFFICER, TODDLER'S CLINICS, BOROUGH OF CAMBERWELL

linics for the advisory care of children aged 2–5 s were instituted in Camberwell, shortly before the , bridging the gap between the infant-welfare and ol medical services. The war closed all these clinics, children were dispersed, and in 1946 it was necessary egin again from scratch.

he response of parents to such a service proved the l which it fulfils, and it seems reasonable to expect a wider and more integrated public-health service make such clinics general throughout the country. work done in them should be described for criticism pædiatricians, administrators, and the general titioners with whom clinics must cooperate.

METHOD

ive clinics were held, with one weekly session each. public health authority possesses, through its health-tor service, a fairly complete list of the child popula-, supplemented by the infant-welfare records.

n invitation signed by the M.O.H. was sent to the nts of every child in the age-group, initially to a on comprising older children returned from evacua- who had not been supervised by the infant-welfare ces in the borough, and later, when a weekly attend- e was being secured, to each parent on the child's hday, the dates being selected monthly to cover the re eligible child population. This method led to an ndance which varied from district to district, seldom eeding 50%. The invitations were followed by onal calls from health visitors, who gave explanations discussed individual problems. The percentage ndance depended most on this follow-up in the nomically poorer zones, and results in general ed a good deal with the personality of the health tor and the previous success of infant-welfare clinics, the most important single factor in securing coöpera- from parents was undoubtedly the propaganda ducted by the mothers who had attended and ived advice.

history

proved simplest, both from the statistical and the medical point, to base the examination on a set questionnaire. h child at its first visit was weighed and measured, and story was taken to cover the following points :

) Personal and family health record.
) Immunisation and vaccination.
) Natal data: labour and neonatal, birth-weight, breast-ing and artificial feeding.
) Ear, nose, and throat: colds, snoring, mouth-breathing, ness, earache, otorrhœa, cough.
) Eyesight, headache, strabismus.
) Appetite and bowel habit.
) Landmarks: walking, talking; left-handedness.
) Sleep, pavor nocturnus, enuresis
) Dental: teething time and dental status.

he same questions were put to each parent in about the e form and order, concluding with " Any pains anywhere?" " Any worries about the child ? "—two blunderbuss stions which evoked the greatest number of missed points. individual history had to be condensed into a routine uiry about acute infections and " any other illnesses or rations." Such relevant points as attacks of nephritis re often volunteered only after pressure, and we soon nt to repeat the question [illegible] e from the health visitor at the reception desk and once from the doctor examining. Family history was covered (not always adequately) by asking " Has anyone on either side of the family had rheumatism, fits, tuberculosis, asthma, or hay-fever ? "—another wide net, which was reached empirically and modified in the asking to the apparent intelligence of the attending parent.

This crude method of history-taking justified itself in dealing with large numbers of predominantly healthy children. Most parents who forgot important facts at the first asking produced them later in the examination.

Physical examination

Besides being weighed and measured, every child was examined for pediculi, postural defects, adenitis, and dental caries. Heart and chest were auscultated; tonsils, teeth, and prepuce were examined; and ears were scrutinised externally, otoscopy being kept, on a basis of experience, for those who had any obscure complaint or a history of recent whooping-cough, tonsillitis, or earache.

Here again the examination was stereotyped at a level of completeness which seemed to us sufficient for the purposes of the clinics, and supplemented on the history. In view of our terms of reference, extra time was better spent on advice and discussion with the parent and in giving health instruction than on physical examination in detail.

One of the chief problems for doctors with little experience in pædiatrics, the class most likely to find themselves doing this work, is to strike a balance between examination and advice in the time available. The routine described here covered all the data required in deciding what to do next. The function of the clinic as a clearing-house, not a thera-peutic centre competing in the normal treatment facilities, had to be kept constantly in mind.

Vollmer tests

Beside this examination, every child was patch-tested for tuberculin-sensitivity by the Vollmer-Goldberg test, and the routine ward tests of urine were noted on the card.

The limitations of this test were fully recognised, but it is not feasible to undertake Mantoux tests involving injection in clinics such as these. The weight of immunisation, vaccina-tion, cod-liver oil, orange-juice, and minor surgery lies heavy upon the attending parent. The test was refused by less than six patients in a year.

In our clinics acetone was used as a cleaning agent, and the patch affixed on the back, where the child could not get at it, with the set formula: " This is a tuberculin test. Don't be scared if it is positive—it doesn't mean that your child will be ill. The test tells us when he first meets tubercle germs, so that we can see that they do not hurt him. Do not get it wet. Take it off the day after tomorrow and bring the child, not the patch, today week." The content of this admonition is an important factor both in the success of the test and in the repute of the clinic in the neighbourhood. When the purpose behind it is explained, with the comment that it is not a form of immunisation, many uninvited parents request a patch-test for the whole family.

We were, and remain, in doubt about the prognostic attitude to take in explaining positive Vollmer tests to the parent. In interpreting negative results we found that the manu-facturers' date-limit was not reliable under our conditions of storage, as exemplified by the falling off of positive readings toward the end of each box. The effective life of a box of patches was finally taken to be about two months. With improved storage this might well be lengthened, but the retention of boxes in stock for a longer time proved too risky.

The age-group at risk was that in which tonsillar and dental defects, rickets, infantile tuberculosis, mild and hence missed mental defect, congenital heart malforma-tions, and acute infections might be expected ; so special precautions were directed to all these. The state of wait-ing-lists in nearby hospitals exerted a beneficial influence in sharpening the criteria for advising tonsillectomy and other forms of surgical treatment. No medicines other than supplements and occasionally oxyuricides were given at the clinics ; detected defects were always referred elsewhere.

Disposal of Cases

All Vollmer-positives were referred direct to the tuberculosis officer at a special session designed to prevent contact with known cases. The poor prognosis in some

the doctor's wife survives him. If a male doctor is unmarried he will receive a retiring allowance three times the value of that granted in the case of a married practitioner. The scheme is a contributory one, and a practitioner will have to pay in 6% of his or her remuneration, the executive council contributing 8% of his remuneration. The rate of remuneration is, of course, not yet calculable as the conditions have not yet been agreed with the profession. For the purpose of this note, however, "remuneration" means all payments made to the practitioner in respect of general medical services provided by him, less a sum for practice expenses, in accordance with a formula laid down by the Minister, and less the remuneration approved by the Minister of any assistant practitioner in his employment. If the practitioner is a partner, and particulars of the partnership agreement are disclosed to the executive council, then his share of the total remuneration of the partnership is equivalent to his share of the partnership profits.

Pensions

The pension to be paid to a practitioner will be on the following scale: (*a*) in respect of each year of contributing service as a practitioner, $1^1/_2$% of his remuneration for that year; (*b*) in respect of each year of contributing service otherwise than as a practitioner 1/80th of his average remuneration at the date on which he last ceased to be employed in such other capacity; and (*c*) in respect of each year of non-contributing service 1/160th of his average remuneration at the date on which he last ceased to be employed in such other capacity. If the contributing service of a practitioner exceeds forty years and he has no service in any other capacity the pension will be calculated by reference to the last forty years of such contributing service.

Retiring Allowance

The retiring allowance to be paid to a practitioner will be the aggregate of the following amounts: (*a*) in respect of each year of contributing service as a practitioner $4^1/_2$% of his remuneration for that year; (*b*) in respect of each year of contributing service otherwise than as a practitioner 3/80ths, and in respect of each year of non-contributing service 3/160ths, in both cases of his average remuneration at the date on which he last ceased to be employed in such other capacity; but in the case of a married male practitioner in respect of whose service a widow's pension may become payable the amount of the retiring allowance will be reduced to 1/3rd.

Widow's Pension

The widow's pension is equivalent to a third of the pension payable to the practitioner or of the amount of pension to which he would have been entitled had he retired on the day preceding his death. It must also be noted, however, that her pension will be reduced or raised according to whether her age was less or greater than that of her husband. It will cease if she remarries.

Qualification for Pension

A doctor will be entitled to his annual pension if he (i) has completed ten years' service and is incapable of discharging his duties through ill health; (ii) has attained the age of sixty and completed ten years' service. He will be entitled to the retiring allowance if he satisfies the conditions in (i) above, or has attained the age of sixty and has completed five years' service.

Death Gratuity

If a practitioner (*a*) dies and at the date of his death had completed five years' service; or (*b*) ceases to be a practitioner after completing five years' service and dies within twelve months after so ceasing, without having received a return of contributions or become entitled to any other benefit under the regulations, and without having again become entitled to participate in superannuation benefits, or (*c*) if he dies after having become entitled to a pension or retiring or injury allowance or short-service gratuity, then the Minister will, subject to certain exceptions, pay a death gratuity of a sum equal to (i) $4^1/_2$% of his remuneration for each year of contributing service as a practitioner or, if widow's pension is payable, $1^1/_2$% thereof; (ii) in of each year of contributing service otherwise th a practitioner 3/80ths of his average remuneratio there is a widow 1/80th) at the date on which he ceased to be employed otherwise than as a practitione and (iii) subject to the same conditions 3/160ths of average remuneration in respect of each year of no contributing service.

Short-service Gratuity

A practitioner who has completed more than five b less than ten years' service, and who ceases to be employ through incapacity to discharge efficiently the dut his employment by reason of permanent ill health infirmity of mind or body, shall, unless he is ent to a retiring allowance, be entitled to a short-se gratuity equal to the amount of his average a remuneration. There is also provision for an i allowance. A practitioner is permitted to allocate of his or her pension or injury allowance to a s or dependant. This will permit women doctors to provision if necessary for their husbands.

Return of Contributions

Contributions with interest may be returned in cer cases, as when a practitioner ceasing to be employ is not entitled to a pension or retiring or injury allow or a short-service gratuity. In case of death, if death gratuity is payable, the legal personal represent tives will be entitled to receive the amount of doctor's contributions with compound interest at $2^1/$ per annum with half-yearly rests.

Life-assurance Policies

Any doctor holding a life-assurance policy may tract out of the scheme by applying to the execu council within three months after the appointed He will then receive 8% of his remuneration a contribution towards his premiums.

Reduction of Pension

The Minister may, subject to medical evide require a person on incapacity pension or injury allowa to return to employment in the scheme—possibly o *part-time employment* with a consequent reduction suspension of the allowance. There is also provision a reduction of a pension on the lines of the local gove ment superannuation scheme where a pensioner ta on further employment remunerated from public fun

Service with the Forces, &c.

CHILDHOOD ADVISORY CLINICS IN CAMBERWELL

ALEX COMFORT
M.B. Camb., D.C.H.
MEDICAL OFFICER, TODDLER'S CLINICS, BOROUGH OF CAMBERWELL

CLINICS for the advisory care of children aged 2–5 ars were instituted in Camberwell, shortly before the , bridging the gap between the infant-welfare and ool medical services. The war closed all these clinics, children were dispersed, and in 1946 it was necessary begin again from scratch.

he response of parents to such a service proved the which it fulfils, and it seems reasonable to expect a wider and more integrated public-health service make such clinics general throughout the country. work done in them should be described for criticism pædiatricians, administrators, and the general ctitioners with whom clinics must cooperate.

METHOD

ive clinics were held, with one weekly session each. e public health authority possesses, through its health-itor service, a fairly complete list of the child popula-, supplemented by the infant-welfare records.

n invitation signed by the M.O.H. was sent to the nts of every child in the age-group, initially to a on comprising older children returned from evacua- who had not been supervised by the infant-welfare vices in the borough, and later, when a weekly attend-e was being secured, to each parent on the child's thday, the dates being selected monthly to cover the re eligible child population. This method led to an endance which varied from district to district, seldom eeding 50%. The invitations were followed by rsonal calls from health visitors, who gave explanations d discussed individual problems. The percentage endance depended most on this follow-up in the nomically poorer zones, and results in general ied a good deal with the personality of the health itor and the previous success of infant-welfare clinics, t the most important single factor in securing coöpera-n from parents was undoubtedly the propaganda ducted by the mothers who had attended and eived advice.

e history

t proved simplest, both from the statistical and the medical wpoint, to base the examination on a set questionnaire. ch child at its first visit was weighed and measured, and istory was taken to cover the following points:

1) Personal and family health record.
2) Immunisation and vaccination.
3) Natal data: labour and neonatal, birth weight, breast-ing and artificial feeding.
4) Ear, nose, and throat: colds, snoring, mouth-breathing, ness, earache, otorrhœa, cough.
5) Eyesight, headache, strabismus.
6) Appetite and bowel habit.
7) Landmarks: walking, talking; left-handedness.
8) Sleep, pavor nocturnus, enuresis.
9) Dental: teething time and dental status.

The same questions were put to each parent in about the me form and order, concluding with "Any pains anywhere?" d "Any worries about the child?"—two blunderbuss estions which evoked the greatest number of missed points. o individual history had to be condensed into a routine uiry about acute infections and "any other illnesses or erations" Such relevant points as attacks of nephritis re often volunteered only after pressure, and we soon rnt to repeat the question, once from the health visitor at the reception desk and once from the doctor examining. Family history was covered (not always adequately) by asking "Has anyone on either side of the family had rheumatism, fits, tuberculosis, asthma, or hay-fever?"—another wide net, which was reached empirically and modified in the asking to the apparent intelligence of the attending parent.

This crude method of history-taking justified itself in dealing with large numbers of predominantly healthy children. Most parents who forgot important facts at the first asking produced them later in the examination.

Physical examination

Besides being weighed and measured, every child was examined for pediculi, postural defects, adenitis, and dental caries. Heart and chest were auscultated; tonsils, teeth, and prepuce were examined; and ears were scrutinised externally, otoscopy being kept, on a basis of experience, for those who had any obscure complaint or a history of recent whooping-cough, tonsillitis, or earache.

Here again the examination was stereotyped at a level of completeness which seemed to us sufficient for the purposes of the clinics, and supplemented on the history. In view of our terms of reference, extra time was better spent on advice and discussion with the parent and in giving health instruction than on physical examination in detail.

One of the chief problems for doctors with little experience in pædiatrics, the class most likely to find themselves doing this work, is to strike a balance between examination and advice in the time available. The routine described here covered all the data required in deciding what to do next. The function of the clinic as a clearing-house, not a thera-peutic centre competing in the normal treatment facilities, had to be kept constantly in mind.

Vollmer tests

Beside this examination, every child was patch-tested for tuberculin-sensitivity by the Vollmer-Goldberg test, and the routine ward tests of urine were noted on the card.

The limitations of this test were fully recognised, but it is not feasible to undertake Mantoux tests involving injection in clinics such as these. The weight of immunisation, vaccina-tion, cod-liver oil, orange-juice, and minor surgery lies heavy upon the attending parent. The test was refused by less than six patients in a year.

In our clinics acetone was used as a cleaning agent, and the patch affixed on the back, where the child could not get at it, with the set formula: "This is a tuberculin test. Don't be scared if it is positive—it doesn't mean that your child will be ill. The test tells us when he first meets tubercle germs, so that we can see that they do not hurt him. Do not get it wet. Take it off the day after tomorrow and bring the child, not the patch, today week." The content of this admonition is an important factor both in the success of the test and in the repute of the clinic in the neighbourhood. When the purpose behind it is explained, with the comment that it is not a form of immunisation, many uninvited parents request a patch-test for the whole family.

We were, and remain, in doubt about the prognostic attitude to take in explaining positive Vollmer tests to the parent. In interpreting negative results we found that the manu-facturers' date-limit was not reliable under our conditions of storage, as exemplified by the falling off of positive readings toward the end of each box. The effective life of a box of patches was finally taken to be about two months. With improved storage this might well be lengthened, but the retention of boxes in stock for a longer time proved too risky.

The age-group at risk was that in which tonsillar and dental defects, rickets, infantile tuberculosis, mild and hence missed mental defect, congenital heart malforma-tions, and acute infections might be expected; so special precautions were directed to all these. The state of wait-ing-lists in nearby hospitals exerted a beneficial influence in sharpening the criteria for advising tonsillectomy and other forms of surgical treatment. No medicines other than supplements and occasionally oxyuricides were given at the clinics; detected defects were always referred elsewhere.

Disposal of Cases

All Vollmer-positives were referred direct to the tuberculosis officer at a special session designed to prevent contact with known cases. The poor prognosis in some

the doctor's wife survives him. If a male doctor is unmarried he will receive a retiring allowance three times the value of that granted in the case of a married practitioner. The scheme is a contributory one, and a practitioner will have to pay in 6% of his or her remuneration, the executive council contributing 8% of his remuneration. The rate of remuneration is, of course, not yet calculable as the conditions have not yet been agreed with the profession. For the purpose of this note, however, "remuneration" means all payments made to the practitioner in respect of general medical services provided by him, less a sum for practice expenses, in accordance with a formula laid down by the Minister, and less the remuneration approved by the Minister of any assistant practitioner in his employment. If the practitioner is a partner, and particulars of the partnership agreement are disclosed to the executive council, then his share of the total remuneration of the partnership is equivalent to his share of the partnership profits.

Pensions

The pension to be paid to a practitioner will be on the following scale: (*a*) in respect of each year of contributing service as a practitioner, $1^1/_2$% of his remuneration for that year; (*b*) in respect of each year of contributing service otherwise than as a practitioner 1/80th of his average remuneration at the date on which he last ceased to be employed in such other capacity; and (*c*) in respect of each year of non-contributing service 1/160th of his average remuneration at the date on which he last ceased to be employed in such other capacity. If the contributing service of a practitioner exceeds forty years and he has no service in any other capacity the pension will be calculated by reference to the last forty years of such contributing service.

Retiring Allowance

The retiring allowance to be paid to a practitioner will be the aggregate of the following amounts: (*a*) in respect of each year of contributing service as a practitioner $4^1/_2$% of his remuneration for that year; (*b*) in respect of each year of contributing service otherwise than as a practitioner 3/80ths, and in respect of each year of non-contributing service 3/160ths, in both cases of his average remuneration at the date on which he last ceased to be employed in such other capacity; but in the case of a married male practitioner in respect of whose service a widow's pension may become payable the amount of the retiring allowance will be reduced to 1/3rd.

Widow's Pension

The widow's pension is equivalent to a third of the pension payable to the practitioner or of the amount of pension to which he would have been entitled had he retired on the day preceding his death. It must also be noted, however, that her pension will be reduced or raised according to whether her age was less or greater than that of her husband. It will cease if she remarries.

Qualification for Pension

A doctor will be entitled to his annual pension if he (i) has completed ten years' service and is incapable of discharging his duties through ill health; (ii) has attained the age of sixty and completed ten years' service. He will be entitled to the retiring allowance if he satisfies the conditions in (i) above, or has attained the age of sixty and has completed five years' service.

Death Gratuity

If a practitioner (*a*) dies and at the date of his death had completed five years' service; or (*b*) ceases to be a practitioner after completing five years' service and dies within twelve months after so ceasing, without having received a return of contributions or become entitled to any other benefit under the regulations, and without having again become entitled to participate in superannuation benefits, or (*c*) if he dies after having become entitled to a pension or retiring or injury allowance or short-service gratuity, then the Minister will, subject to certain exceptions, pay a death gratuity of a sum equal to (i) $4^1/_2$% of his remuneration for each year of contributing service as a practitioner or, if widow's pension is payable, $1^1/_2$% thereof; (ii) in respect of each year of contributing service otherwise than a practitioner 3/80ths of his average remuneration there is a widow 1/80th) at the date on which he ceased to be employed otherwise than as a practitioner and (iii) subject to the same conditions 3/100ths of average remuneration in respect of each year of non contributing service.

Short-service Gratuity

A practitioner who has completed more than five less than ten years' service, and who ceases to be employ through incapacity to discharge efficiently the duti his employment by reason of permanent ill infirmity of mind or body, shall, unless he is to a retiring allowance, be entitled to a shor gratuity equal to the amount of his average remuneration. There is also provision for an allowance. A practitioner is permitted to allo of his or her pension or injury allowance to a or dependant. This will permit women doctors to provision if necessary for their husbands.

Return of Contributions

Contributions with interest may be returned in cert cases, as when a practitioner ceasing to be employ is not entitled to a pension or retiring or injury allowa or a short-service gratuity. In case of death, if death gratuity is payable, the legal personal represen tives will be entitled to receive the amount of doctor's contributions with compound interest at $2^1/$ per annum with half-yearly rests.

Life-assurance Policies

Any doctor holding a life-assurance policy may tract out of the scheme by applying to the execu council within three months after the appointed He will then receive 8% of his remuneration contribution towards his premiums.

Reduction of Pension

The Minister may, subject to medical eviden require a person on incapacity pension or injury allowa to return to employment in the scheme—possibly part-time employment with a consequent reduction suspension of the allowance. There is also provision a reduction of a pension on the lines of the local gover ment superannuation scheme where a pensioner ta on further employment remunerated from public fun

Service with the Forces, &c.

Provision is made for continuation in the sche during service with the Armed Forces, but this seems be prospective, not retrospective.

Service in various forms of employment will be coun towards superannuation benefits. Contributing serv covers service in respect of which the practitioner made the contributions required by the regulations p previous employment if falling within certain definit It does not appear, however, that service as a Nation Health Insurance practitioner can be aggregated. No contributory service is defined in the regulations follows: There shall be reckonable as non-contributo service in relation to the employment of an officer an employing authority any service which is not reck able as contributing service and which is not reck solely for the purpose of determining whether benefit is payable under the regulations. This somewh involved section will doubtless be clarified later.

The scheme will be administered by a Health Se Superannuation Division of the Ministry of Health, 28, Princes Gate, London, S.W.7. It will be by contributions from the participants in its benefits by contributions from the Exchequer. It will not funded but will be subjected to actuarial invest periodically at seven-year intervals.

CHILDHOOD ADVISORY CLINICS IN CAMBERWELL

ALEX COMFORT
M.B. Camb., D.C.H.
MEDICAL OFFICER, TODDLER'S CLINICS, BOROUGH OF CAMBERWELL

LINICS for the advisory care of children aged 2–5 rs were instituted in Camberwell, shortly before the r, bridging the gap between the infant-welfare and ool medical services. The war closed all these clinics, children were dispersed, and in 1946 it was necessary begin again from scratch.

The response of parents to such a service proved the d which it fulfils, and it seems reasonable to expect a wider and more integrated public-health service make such clinics general throughout the country. work done in them should be described for criticism pædiatricians, administrators, and the general ctitioners with whom clinics must cooperate.

METHOD

Five clinics were held, with one weekly session each. e public health authority possesses, through its health-itor service, a fairly complete list of the child popula-n, supplemented by the infant-welfare records.

An invitation signed by the M.O.H. was sent to the nts of every child in the age-group, initially to a on comprising older children returned from evacua- who had not been supervised by the infant-welfare vices in the borough, and later, when a weekly attend-e was being secured, to each parent on the child's thday, the dates being selected monthly to cover the ire eligible child population. This method led to an endance which varied from district to district, seldom eeding 50%. The invitations were followed by rsonal calls from health visitors, who gave explanations d discussed individual problems. The percentage endance depended most on this follow-up in the nomically poorer zones, and results in general ried a good deal with the personality of the health itor and the previous success of infant-welfare clinics, t the most important single factor in securing coöpera-n from parents was undoubtedly the propaganda nducted by the mothers who had attended and eived advice.

e history

It proved simplest, both from the statistical and the medical point, to base the examination on a set questionnaire. ch child at its first visit was weighed and measured, and story was taken to cover the following points:

1) Personal and family health record.
2) Immunisation and vaccination.
3) Natal data: labour and neonatal, birth-weight, breast-ding and artificial feeding.
4) Ear, nose, and throat: colds, snoring, mouth-breathing, ness, earache, otorrhœa, cough.
5) Eyesight, headache, strabismus.
6) Appetite and bowel habit.
7) Landmarks: walking, talking; left-handedness.
8) Sleep, pavor nocturnus, enuresis.
9) Dental: teething time and dental status.

The same questions were put to each parent in about the me form and order, concluding with "Any pains anywhere?" d "Any worries about the child?"—two blunderbuss stions which evoked the greatest number of missed points. he individual history had to be condensed into a routine quiry about acute infections and "any other illnesses or erations." Such relevant points as attacks of nephritis ere often volunteered only after pressure, and we soon arnt to ice from the health visitor at the reception desk and once from the doctor examining. Family history was covered (not always adequately) by asking 'Has anyone on either side of the family had rheumatism, fits, tuberculosis, asthma, or hay-fever?"—another wide net, which was reached empirically and modified in the asking to the apparent intelligence of the attending parent.

This crude method of history-taking justified itself in dealing with large numbers of predominantly healthy children. Most parents who forgot important facts at the first asking produced them later in the examination.

Physical examination

Besides being weighed and measured, every child was examined for pediculi, postural defects, adenitis, and dental caries. Heart and chest were auscultated; tonsils, teeth, and prepuce were examined; and ears were scrutinised externally, otoscopy being kept, on a basis of experience, for those who had any obscure complaint or a history of recent whooping-cough, tonsillitis, or earache.

Here again the examination was stereotyped at a level of completeness which seemed to us sufficient for the purposes of the clinics, and supplemented on the history. In view of our terms of reference, extra time was better spent on advice and discussion with the parent and in giving health instruction than on physical examination in detail.

One of the chief problems for doctors with little experience in pædiatrics, the class most likely to find themselves doing this work, is to strike a balance between examination and advice in the time available. The routine described here covered all the data required in deciding what to do next. The function of the clinic as a clearing-house, not a therapeutic centre competing in the normal treatment facilities, had to be kept constantly in mind.

Vollmer tests

Beside this examination, every child was patch-tested for tuberculin-sensitivity by the Vollmer-Goldberg test, and the routine ward tests of urine were noted on the card.

The limitations of this test were fully recognised, but it is not feasible to undertake Mantoux tests involving injection in clinics such as these. The weight of immunisation, vaccination, cod-liver oil, orange-juice, and minor surgery lies heavy upon the attending parent. The test was refused by less than six patients in a year.

In our clinics acetone was used as a cleaning agent, and the patch affixed on the back, where the child could not get at it, with the set formula: "This is a tuberculin test. Don't be scared if it is positive—it doesn't mean that your child will be ill. The test tells us when he first meets tubercle germs, so that we can see that they do not hurt him. Do not get it wet. Take it off the day after tomorrow and bring the child, not the patch, today week." The content of this admonition is an important factor both in the success of the test and in the repute of the clinic in the neighbourhood. When the purpose behind it is explained, with the comment that it is not a form of immunisation, many uninvited parents request a patch-test for the whole family.

We were, and remain, in doubt about the prognostic attitude to take in explaining positive Vollmer tests to the parent. In interpreting negative results we found that the manufacturers' date-limit was not reliable under our conditions of storage, as exemplified by the falling off of positive readings toward the end of each box. The effective life of a box of patches was finally taken to be about two months. With improved storage this might well be lengthened, but the retention of boxes in stock for a longer time proved too risky.

The age-group at risk was that in which tonsillar and dental defects, rickets, infantile tuberculosis, mild and hence missed mental defect, congenital heart malformations, and acute infections might be expected; so special precautions were directed to all these. The state of waiting-lists in nearby hospitals exerted a beneficial influence in sharpening the criteria for advising tonsillectomy and other forms of surgical treatment. No medicines other than supplements and occasionally oxyuricides were given at the clinics; detected defects were always referred elsewhere.

Disposal of Cases

All Vollmer-positives were referred direct to the tuberculosis officer at a special session designed to prevent contact with known cases. The poor prognosis in some

the doctor's wife survives him. If a male doctor is unmarried he will receive a retiring allowance three times the value of that granted in the case of a married practitioner. The scheme is a contributory one, and a practitioner will have to pay in 6 % of his or her remuneration, *the executive council contributing 8 % of his* remuneration. The rate of remuneration is, of course, not yet calculable as the conditions have not yet been agreed with the profession. For the purpose of this note, however, "remuneration" means all payments made to the practitioner in respect of general medical services provided by him, less a sum for practice expenses, in accordance with a formula laid down by the Minister, and less the remuneration approved by the Minister of any assistant practitioner in his employment. If the practitioner is a partner, and particulars of the partnership agreement are disclosed to the executive council, then his share of the total remuneration of the partnership is equivalent to his share of the partnership profits.

Pensions

The pension to be paid to a practitioner will be on the following scale: (*a*) in respect of each year of contributing service as a practitioner, $1^1/_2$ % of his remuneration for that year; (*b*) in respect of each year of contributing service otherwise than as a practitioner 1/80th of his average remuneration at the date on which he last ceased to be employed in such other capacity; and (*c*) in respect of each year of non-contributing service 1/160th of his average remuneration at the date on which he last ceased to be employed in such other capacity. If the contributing service of a practitioner *exceeds forty years and he has no service in any other* capacity the pension will be calculated by reference to the last forty years of such contributing service.

Retiring Allowance

The retiring allowance to be paid to a practitioner will be the aggregate of the following amounts: (*a*) in respect of each year of contributing service as a practitioner $4^1/_2$ % of his remuneration for that year; (*b*) in respect of each year of contributing service otherwise than as a practitioner 3/80ths, and in respect of each year of non-contributing service 3/160ths, in both cases of his average remuneration at the date on which he last ceased to be employed in such other capacity; but in the case of a married male practitioner in respect of whose service a widow's pension may become payable the amount of the retiring allowance will be reduced to 1/3rd.

Widow's Pension

The widow's pension is equivalent to a third of the pension payable to the practitioner or of the amount of pension to which he would have been entitled had he retired on the day preceding his death. It must also be noted, however, that her pension will be reduced or raised according to whether her age was less or greater than that of her husband. It will cease if she remarries.

Qualification for Pension

A doctor will be entitled to his annual pension if he (i) has completed ten years' service and is incapable of discharging his duties through ill health; (ii) has attained the age of sixty and completed ten years' service. He will be entitled to the retiring allowance if he satisfies the conditions in (i) above, or has attained the age of sixty and has completed five years' service.

Death Gratuity

If a practitioner (*a*) dies and at the date of his death had completed five years' service; or (*b*) ceases to be a practitioner after completing five years' service and dies within twelve months after so ceasing, without having received a return of contributions or become entitled to any other benefit under the regulations, and without having again become entitled to participate in superannuation benefits, or (*c*) if he dies after having become entitled to a pension or retiring or injury allowance or short-service gratuity, then the Minister will, subject to certain exceptions, pay a death gratuity of a sum equal to (i) $4^1/_2$ % of his remuneration for each year of contributing service as a practitioner or, if widow's pension is payable, $1^1/_2$ % thereof; (ii) in re of each year of contributing service otherwise than a practitioner 3/80ths of his average remuneratio there is a widow 1/80th) at the date on which he ha *ceased to be employed otherwise* than as a practitioner and (iii) subject to the same conditions 3/160ths of h average remuneration in respect of each year of no contributing service.

Short-service Gratuity

A practitioner who has completed more than five less than ten years' service, and who ceases to be employ through incapacity to discharge efficiently the duties his employment by reason of permanent ill h infirmity of mind or body, shall, unless he is to a retiring allowance, be entitled to a short gratuity equal to the amount of his average remuneration. There is also provision for an allowance. A practitioner is permitted to allo of his or her pension or injury allowance to a or dependant. This will permit women doctors to provision if necessary for their husbands.

Return of Contributions

Contributions with interest may be returned in cer cases, as when a practitioner ceasing to be employ is not entitled to a pension or retiring or injury allowa or a short-service gratuity. In case of death, if death gratuity is payable, the legal personal represent tives will be entitled to receive the amount of doctor's contributions with compound interest at $2^1/_2$ per annum with half-yearly rests.

Life-assurance Policies

Any doctor holding a life-assurance policy may tract out of the scheme by applying to the execu council within three months after the appointed d He will then receive 8 % of his remuneration a contribution towards his premiums.

Reduction of Pension

The Minister may, subject to medical eviden require a person on incapacity pension or injury allowa to return to employment in the scheme—possibly o part-time employment with a consequent reduction suspension of the allowance. There is also provision f *a reduction of a pension on the lines of the* local gover ment superannuation scheme where a pensioner ta on further employment remunerated from public fun

Service with the Forces, &c.

Provision is made for continuation in the sche during service with the Armed Forces, but this seems be prospective, not retrospective.

Service in various forms of employment will be coun towards superannuation benefits. Contributing serv covers service in respect of which the practitioner h made the contributions required by the regulations pl previous employment if falling within certain definitio It does not appear, however, that service as a Nation Health Insurance practitioner can be aggregated. No *contributory service is defined in the* regulations follows: There shall be reckonable as non-contributor service in relation to the employment of an officer an employing authority any service which is not reck able as contributing service and which is not reckonabl solely for the purpose of determining whether benefit is payable under the regulations. This somewh involved section will doubtless be clarified later.

The scheme will be administered by a Health Se Superannuation Division of the Ministry of Health, 28, Princes Gate, London, S.W.7. It will be by contributions from the participants in its benefits by contributions from the Exchequer. It will not funded but will be subjected to actuarial invest periodically at seven-year intervals.

METHOD

re clinics were held, with one weekly session each. public health authority possesses, through its health- or service, a fairly complete list of the child popula- supplemented by the infant-welfare records.

n invitation signed by the M.O.H. was sent to the nts of every child in the age-group, initially to a on comprising older children returned from evacua- who had not been supervised by the infant-welfare ces in the borough, and later, when a weekly attend- was being secured, to each parent on the child's day, the dates being selected monthly to cover the e eligible child population. This method led to an dance which varied from district to district, seldom eding 50%. The invitations were followed by onal calls from health visitors, who gave explanations discussed individual problems. The percentage ndance depended most on this follow-up in the omically poorer zones, and results in general ed a good deal with the personality of the health tor and the previous success of infant-welfare clinics, the most important single factor in securing coöpera- from parents was undoubtedly the propaganda ducted by the mothers who had attended and ived advice.

istory

proved simplest, both from the statistical and the medical point, to base the examination on a set questionnaire. h child at its first visit was weighed and measured, and tory was taken to cover the following points :

) Personal and family health record.
) Immunisation and vaccination.
) Natal data: labour and neonatal, birth-weight, breast- g and artificial feeding.
) Ear, nose, and throat: colds, snoring, mouth-breathing, ess, earache, otorrhœa, cough.
i) Eyesight, headache, strabismus.
i) Appetite and bowel habit.
) Landmarks: walking, talking; left-handedness.
) Sleep, pavor nocturnus, enuresis.
) Dental: teething time and dental status.

he same questions were put to each parent in about the form and order, concluding with "Any pains anywhere?" "Any worries about the child?"—two blunderbuss tions which evoked the greatest number of missed points. e individual history had to be condensed into a routine uiry about acute infections and "any other illnesses or tions." Such relevant points as attacks of nephritis e often volunteered only after pressure, and we soon nt to repeat the question, once from the health visitor at the reception desk and once from the doctor examining. Family history was covered (not always adequately) by asking "Has anyone on either side of the family had rheumatism, fits, tuberculosis, asthma, or hay-fever?"—another wide net, which was reached empirically and modified in the asking to the apparent intelligence of the attending parent.

This crude method of history-taking justified itself in dealing with large numbers of predominantly healthy children. Most parents who forgot important facts at the first asking produced them later in the examination.

Physical examination

Besides being weighed and measured, every child was examined for pediculi, postural defects, adenitis, and dental caries. Heart and chest were auscultated; tonsils, teeth, and prepuce were examined; and ears were scrutinised externally, otoscopy being kept, on a basis of experience, for those who had any obscure complaint or a history of recent whooping-cough, tonsillitis, or earache.

Here again the examination was stereotyped at a level of completeness which seemed to us sufficient for the purposes of the clinics, and supplemented on the history. In view of our terms of reference, extra time was better spent on advice and discussion with the parent and in giving health instruction than on physical examination in detail.

One of the chief problems for doctors with little experience in pædiatrics, the class most likely to find themselves doing this work, is to strike a balance between examination and advice in the time available. The routine described here covered all the data required in deciding what to do next. The function of the clinic as a clearing-house, not a therapeutic centre competing in the normal treatment facilities, had to be kept constantly in mind.

Vollmer tests

Beside this examination, every child was patch-tested for tuberculin-sensitivity by the Vollmer-Goldberg test, and the routine ward tests of urine were noted on the card.

The limitations of this test were fully recognised, but it is not feasible to undertake Mantoux tests involving injection in clinics such as these. The weight of immunisation, vaccination, cod-liver oil, orange-juice, and minor surgery lies heavy upon the attending parent. The test was refused by less than six patients in a year.

In our clinics acetone was used as a cleaning agent, and the patch affixed on the back, where the child could not get at it, with the set formula: "This is a tuberculin test. Don't be scared if it is positive—it doesn't mean that your child will be ill. The test tells us when he first meets tubercle germs, so that we can see that they do not hurt him. Do not get it wet. Take it off the day after tomorrow and bring the child, not the patch, today week." The content of this admonition is an important factor both in the success of the test and in the repute of the clinic in the neighbourhood. When the purpose behind it is explained, with the comment that it is not a form of immunisation, many uninvited parents request a patch-test for the whole family.

We were, and remain, in doubt about the prognostic attitude to take in explaining positive Vollmer tests to the parent. In interpreting negative results we found that the manufacturers' date-limit was not reliable under our conditions of storage, as exemplified by the falling off of positive readings toward the end of each box. The effective life of a box of patches was finally taken to be about two months. With improved storage this might well be lengthened, but the retention of boxes in stock for a longer time proved too risky.

The age-group at risk was that in which tonsillar and dental defects, rickets, infantile tuberculosis, mild and hence missed mental defect, congenital heart malformations, and acute infections might be expected; so special precautions were directed to all these. The state of waiting-lists in nearby hospitals exerted a beneficial influence in sharpening the criteria for advising tonsillectomy and other forms of surgical treatment. No medicines other than supplements and occasionally oxyuricides were given at the clinics; detected defects were always referred elsewhere.

Disposal of Cases

All Vollmer-positives were referred direct to the tuberculosis officer at a special session designed to prevent contact with known cases. The poor prognosis in some

published series of hospital cases is in part the product of non-notification, designed to avoid the "stigma" of tuberculosis, which leads to non-detection of contacts and to the return of the sensitised child to an infected milieu. The most serious obstacle to the work of both the clinics and the tuberculosis officers seemed to be the slowness with which patients could be placed in sanatoria; so patients with plainly active tuberculosis were sometimes referred by us directly to general hospitals.

The disposal of patients with other diseases raised unanticipated problems of professional conduct. Most of the patients already attended private practitioners, and, where possible, defects were referred to them; but the impossibility of securing a follow-up, combined with the attitude of certain patients who did not let us know that they were already under treatment, complicated the issue. There was a strong tendency for patients to use the clinics to check their own doctor's treatment and to get to hospital in spite of his advice; we did our best, when we detected this, to discourage it. The full coöperation of most local doctors did not always save us from invidious decisions, and we ended by referring directly to voluntary hospitals most cases requiring treatment. This was defensible, in our view, only because of the peculiar position which such clinics, publicly financed and publicly canvassed, must needs occupy, and we make no claim to have solved fully or satisfactorily the problems of coöperation with the general medical services outside the borough scheme—the blame, if any, rests not on the practitioners but on the inherent difficulties of any dual system.

We never advised tonsillectomy or other surgical treatment directly; we referred all cases which might require it for a surgical opinion. Dental treatment and eye refractions were undertaken through the L.C.C. minor-ailments scheme. All cases of ankle-weakness and knock-knee severe enough to need treatment and all cases of speech defect were referred to a voluntary hospital. The clinics accordingly functioned as a clearing-house and advisory centre, especially the latter.

Distribution of Drugs and Supplements

The clinics also acted as distributing centres for Ministry of Food supplements and dietetic extras provided through the borough. Complaints of poor tolerance were investigated and, where reasonable, capsules and concentrates substituted for Government oil, and other sources of vitamin C for orange-juice. The acceptance of these by the public was uniformly good, though the higher income-groups preferred dear proprietaries of low antirachitic value to free or cheap cod-liver oil.

The cases showing active or recent rickets were few. Our criteria (not usually confirmed by radiography) were those given by Hamilton et al.[1] (delayed dentition, hypotonia, head-sweating, and delayed walking), since our purpose was prevention rather than investigation. The remark about injection at clinics applies to the investigation of vitamin-C deficiencies; in a private series of similar range it would have been possible to use Slobody's intradermal tests on a mass scale, but this would have destroyed the other and more valuable work of the clinics.

Scope of Work

We found limitation of the effective scope of work undertaken in the clinic to be one of the prime conditions of success. In planning this scope we estimated that a maximum of 15 cases would be seen in a session of two hours, allowing for the shorter time occupied in dealing with return visits. To derive the greatest value from the time at our disposal, we needed to adopt a very different approach from that of the diagnostician in or out of hospital, who conducts the treatment but ceases to supervise the case as so normality is restored. We had to deal with and prevention, particularly with the fo conditions likely to need surgery; and, though data were collected, we did not pursue data for own sake: we did not, for instance, control all of suspected rickets by X rays or chemistry—not indiscriminate dosing with supplements has any cation, but because of the importance of deficiency *on one hand and* sparing the parent on other. So long as hospital attendance involves a which in many cases exceeded six hours from the lished time of the clinic (cases where patients at 9 A.M. for a short consultation or investigation not seen until late afternoon were common, hospitals of national standing in pædiatrics), the control of supplements must wait until there are facilities for investigation in the health-centre We relied chiefly on hospitals which had insti appointment system. Apart from this fact, we a principle to devote time rather to advising the of normal children on general and minor problems to giving special advice where patients were found be clinically ill.

The system of fixed "skeleton" case-taking dir at the commonest undetected or symptomless ab malities, with immediate reference back of cases, as as provisionally diagnosed, for treatment and inves tion elsewhere, suited the function for which the cl were designed. In all cases the reports of other ins tions were filed in our records and we resumed superv of the case at the point where it was discharged specialist care.

FINDINGS

Higher wages, evacuation and the bombing of sl Government supplements to diet, and improved he education have borne remarkable fruit in the phy state of London children. At the same time conscrip the universal cheapening of human responsibility, small family, gross housing deficiencies (especially attempt to rear children in flats), and the fraying parental nerves through shortages and enforced sex deprivation have contributed a psychological d balance.

Rickets.—Out of some 2500 children examined not m than 24 were on clinical findings grossly rachitic, th perhaps 100 needed greatly improved nutrition, and a p centage showing clear evidence of neglect hinted at existence *of other neglected* children whose parents unlikely to bring them voluntarily to attend at clinics.

Tuberculosis, where Vollmer reversal took place under eyes, was generally traceable to a close home contact or visit to the country. Our results were another proof of value of routine child tests in detecting adult disease.

Weights and heights compared favourably with pre figures. The most salient deficiencies were all minor; extreme disorganisation of war made this a very po vaccinated population (less than 50%), though immunis reached 90% in some clinic zones and refusals in the atten group were uncommon. We have deliberately exclu tables, since the voluntary character of the attendance m it important that our figures should not be taken as an sample.

Scabies was very rare; *pediculosis* moderately common.

Dental caries tended to appear in 30% of cases about third year, and predominantly affected the incisors. were divided into those where defective enamel-form led to incisor caries at gum-level, those showing symm first-molar cavities, and those showing both. Parents perhaps least coöperative in accepting conservative on deciduous teeth, even when dentists had declined extract and explained the reasons for the decision. instances of striking neglect were found in otherwise intel families, one child having five active and palpable abs

Phimosis.—The many cases of avoidable phimosis children who had not attended infant-welfare clinics

r ; minor disorders of behaviour ; and " nervous-
." There was no great incidence of unmanageability
age-group was not suitable for conclusions on " delin-
nt " reactions, and the period of exposure to parental
rosis had been from birth to early childhood, not
n early childhood to prepuberty). Nervousness and
chogenic troubles were almost uniformly attributed
parents to prenatal trauma by bombs, and equally
uniformly traceable to parental neurosis, of which obsessional manifestations did, on the whole, most damage and anxiety states made up the major part. In two cases we sent the children for " guidance "—in all the others requiring treatment we referred the parents directly to the psychiatrist.

Parental neurosis proved to be our most contagious disease, and one to which children possessed no resistance whatever. Its incidence is by far the highest in the better educated family group. Some of the happiest and healthiest of our children were adopted, chiefly in working homes. Of the causes of parental trouble, conscription and its effects came first and lack of sexual and contraceptive knowledge second, followed closely by housing deficiencies. Economic fears were not significantly represented. The clinics spent as much time on minor psychiatry as on all the other activities put together. Even in the children who remained in London, bombing, as an experience, did far less damage than tonsillectomy or brusque treatment in hospital, a point which must be borne in mind when surgery is being considered.

Ignorance and Error

Parental education varied, and health knowledge (and superstition) with it. It is of more social than medical interest, perhaps, that over three-quarters of mothers " touched wood " when asked for details of past infection. This xylolatry, as it might be called, was general among unbelievers in immunisation.

Two of our chief enemies were proprietary infant powders and camphorated-oil rubs, the first as a cause of obstinate bowel atony, and the second as a source of macules, papules, and pustules.

The campaign for vitamins has produced more zeal than instruction, and a good many mothers are ready to substitute for the official concentrates not only fortified infant foods and " body-builders " but also unfortified iron tonics, irrespective of whether vitamins are being received from other sources.

Most cases of intolerance to cod-liver oil were due to management, but a few were genuine fat-intolerance, and there was a definite incidence of allergic responses to orange-juice.

Castor oil still figures occasionally as a weekly dose for young children, and as a specific for bellyache, and the prevalence of enemas for oxyuriasis continues, with some professional backing. It had usually caused more trouble in our cases than the parasites, and parental good sense terminated treatment in most cases.

So many superstitions have been attacked by hygiene teaching that the relation between stammer and left-handedness needed to be reasserted in a good many instances, where parents regarded it as another unlikely story.

Complaints about National bread as a cause of childhood troubles bore a definite political distribution, and complaints about housing, with more foundation, were adduced in most cases of respiratory trouble.

The clinics were used largely as a source of health teaching, by posters, films, and admonition ; and clothing, foods, pamphlets, and demonstrations were shown by the health visitors, generally with good result.

WEAKNESSES

Our main weakness was probably our fragmentary attitude to the family. Since it is not practicable to see at such a clinic more than the mother and one or perhaps two children of about the same age, treatment of the kind we could give lacks a proper diagnostic basis. The family is an ecological unit. If we could have supervised the entire group on Peckham lines, or enjoyed the same facilities as the family doctor, we could have done more. In most cases, throughout all income groups, we found that the practitioner or, more often, practitioners, were used more as one employs a plumber than as family consultants. War and migration had so largely destroyed the family unit of practice that we were constantly called to integrate treatment where mother, children, and father were attended severally (and, it appeared, in strict secrecy) by separate doctors and by two or three hospitals, and our clinics were added to the collection of opinions

published series of hospital cases is in part the product of non-notification, designed to avoid the "stigma" of tuberculosis, which leads to non-detection of contacts and to the return of the sensitised child to an infected milieu. This was defensible, in our view, only because of the peculiar position which such clinics, publicly financed and publicly canvassed, must needs occupy, and we make no claim to have solved fully or satisfactorily the problems of coöperation with the general medical services outside the borough scheme—the blame, if any, rests not on the practitioners but on the inherent difficulties of any dual system.

We never advised tonsillectomy or other surgical treatment directly; we referred all cases which might require it for a surgical opinion. Dental treatment and eye refractions were undertaken through the L.C.C. minor-ailments scheme. All cases of ankle-weakness and knock-knee severe enough to need treatment and all cases of speech defect were referred to a voluntary hospital. The clinics accordingly functioned as a clearing-house and advisory centre, especially the latter.

Distribution of Drugs and Supplements

The clinics also acted as distributing centres for Ministry of Food supplements and dietetic extras provided through the borough. Complaints of poor tolerance were investigated and, where reasonable, capsules and concentrates substituted for Government oil, and other sources of vitamin C for orange-juice. The acceptance of these by the public was uniformly good, though the higher income-groups preferred dear proprietaries of low antirachitic value to free or cheap cod-liver oil.

The cases showing active or recent rickets were few. Our criteria (not usually confirmed by radiography) were those given by Hamilton et al.[1] (delayed dentition, hypotonia, head-sweating, and delayed walking), since our purpose was prevention rather than investigation. The remark about injection at clinics applies to the investigation of vitamin-C deficiencies; in a private series of similar range it would have been possible to use Slobody's intradermal tests on a mass scale, but this would have destroyed the other and more valuable work of the clinics.

Scope of Work

We found limitation of the effective scope of work undertaken in the clinic to be one of the prime conditions of success. In planning this scope we estimated that a maximum of 15 cases would be seen in a session of two hours, allowing for the shorter time occupied in dealing with return visits. To derive the greatest value from the time at our disposal, we needed to adopt a very different approach from that of the diagnostician in or out of hospital, who conducts the treatment but ceases to supervise the case as normality is restored. We had to deal with and prevention, particularly with the forest conditions likely to need surgery; and, though data were collected, we did not pursue data for own sake: we did not, for instance, control all of suspected rickets by X rays or chemistry—not indiscriminate dosing with supplements has any cation, but because of the importance of pr deficiency on one hand and sparing the parent on other. So long as hospital attendance involves a which in many cases exceeded six hours from the lished time of the clinic (cases where patients at at 9 A.M. for a short consultation or investigation not seen until late afternoon were common, hospitals of national standing in pædiatrics), the control of supplements must wait until there are facilities for investigation in the health-centre pr We relied chiefly on hospitals which had inst appointment system. Apart from this fact, we a principle to devote time rather to advising the of normal children on general and minor problems to giving special advice where patients were fo be clinically ill.

The system of fixed "skeleton" case-taking dire at the commonest undetected or symptomless ab malities, with immediate reference back of cases, as as provisionally diagnosed; for treatment and in tion elsewhere, suited the function for which the were designed. In all cases the reports of other ins tions were filed in our records and we resumed superv of the case at the point where it was discharged specialist care.

FINDINGS

Higher wages, evacuation and the bombing of sl Government supplements to diet, and improved he education have borne remarkable fruit in the phy state of London children. At the same time conscript the universal cheapening of human responsibility, small family, gross housing deficiencies (especially attempt to rear children in flats), and the fraying parental nerves through shortages and enforced sex deprivation have contributed a psychological d balance.

Rickets.—Out of some 2500 children examined not than 24 were on clinical findings grossly rachitic, the perhaps 100 needed greatly improved nutrition, and a centage showing clear evidence of neglect hinted at existence of other neglected children whose parents unlikely to bring them voluntarily to attend at clinics.

Tuberculosis, where Vollmer reversal took place under eyes, was generally traceable to a close home contact or visit to the country. Our results were another proof of value of routine child tests in detecting adult disease.

Weights and heights compared favourably with pre- figures. The most salient deficiencies were all minor; extreme disorganisation of war made this a very po vaccinated population (less than 50%), though immunis reached 90% in some clinic zones and refusals in the atten group were uncommon. We have deliberately tables, since the voluntary character of the attendance it important that our figures should not be taken as an o sample.

Scabies was very rare; *pediculosis* moderately common.

Dental caries tended to appear in 30% of cases about third year, and predominantly affected the incisors C were divided into those where defective enamel-fo led to incisor caries at gum-level, those showing first-molar cavities, and those showing both. tal Coöperation

e standard of parental coöperation was high, even the voluntary attendance is taken into considera- The mothers with whom we had to deal had been cted to various external and internal stresses ; but, ever deterioration has taken place in the environ- of the family, some of the fruit of pre-war psycho- l and hygienic instruction is fairly obvious in our dance. Sanity of attitude toward enuresis, mastur- n, jealousies in the family, and the conception of pline is largely an outcome of such past teaching. t, we found evidence to support the view put for- l by Halliday that future effort in advisory clinics be needed to counteract over-enthusiastic ideas of ene rather than to instil new ones.

essional patterns in mothers thwarted over the el habit or appetite of their children are certainly monest in the intelligent and the hygienically led. We often conducted propaganda for rather more hy dirt, constipation, and anorexia. "I've kept on his pot for two hours, he's that stubborn," is a mark in the deformation of a personality, though in ses the child generally won. We shall have to see the decay of a coercive morality does not leave for the growth of an equally coercive and irrational of the time-table in childhood. The danger is ased in circumstances where pre-school children it flats in ones or two's, without safe facilities for munal play. The higher physical standard of housing hese flats is more than offset by the consequences he child.

ily Planning

e encountered much spontaneous comment on the h-rate problem in reply to the question "How many lren ?" The reasons adduced for limiting the family strikingly uniform, war coming first, fear of renewed second, and the consequences of war, particularly ting, third, followed by economic considerations. they want us to have children, they can stop our leaking" ; "It's no world for children, we think" ; od time" and health reasons were not common, and gh proportion of women with a rheumatic heart three or more children by choice in the face of r appreciation of the physical result.

ptoms Complained of

norexia in only children probably heads the list of plaints ; and here we made much use of the leaflet ed by the National Council for Health Education. istent cough, dating from measles or an infection, e second, the cases falling fairly definitely into a illar group, an allergic group, and a "mixed bag," ng the severer members of which we searched ematically for latent bronchiectasis, and of these suspect cases passed out of our hands for broncho- phy and other investigation.

he third major group was psychological : enuresis, hich parental reactions seem to be much improved ; or ; minor disorders of behaviour ; and "nervous- s." There was no great incidence of unmanageability age group was not suitable for conclusions on "delin- nt" reactions, and the period of exposure to parental rosis had been from birth to early childhood, not m early childhood to prepuberty). Nervousness and chogenic troubles were almost uniformly attributed parents to prenatal trauma by bombs, and equally uniformly traceable to parental neurosis, of which obsessional manifestations did, on the whole, most damage and anxiety states made up the major part. In two cases we sent the children for "guidance"—in all the others requiring treatment we referred the parents directly to the psychiatrist.

Parental neurosis proved to be our most contagious disease, and one to which children possessed no resistance whatever. Its incidence is by far the highest in the better educated family group. Some of the happiest and healthiest of our children were adopted, chiefly in working homes. Of the causes of parental trouble, conscription and its effects came first and lack of sexual and contraceptive knowledge second, followed closely by housing deficiencies. Economic fears were not significantly represented. The clinics spent as much time on minor psychiatry as on all the other activities put together. Even in the children who remained in London, bombing, as an experience, did far less damage than tonsillectomy or brusque treatment in hospital, a point which must be borne in mind when surgery is being considered.

Ignorance and Error

Parental education varied, and health knowledge (and superstition) with it. It is of more social than medical interest, perhaps, that over three-quarters of mothers "touched wood" when asked for details of past infection. This xylolatry, as it might be called, was general among unbelievers in immunisation.

Two of our chief enemies were proprietary infant powders and camphorated-oil rubs, the first as a cause of obstinate bowel atony, and the second as a source of macules, papules, and pustules.

The campaign for vitamins has produced more zeal than instruction, and a good many mothers are ready to substitute for the official concentrates not only fortified infant foods and "body-builders" but also unfortified iron tonics, irrespective of whether vitamins are being received from other sources.

Most cases of intolerance to cod-liver oil were due to management, but a few were genuine fat-intolerance, and there was a definite incidence of allergic responses to orange-juice.

Castor oil still figures occasionally as a weekly dose for young children, and as a specific for bellyache, and the prevalence of enemas for oxyuriasis continues, with some professional backing. It had usually caused more trouble in our cases than the parasites, and parental good sense terminated treatment in most cases.

So many superstitions have been attacked by hygiene teaching that the relation between stammer and left-handedness needed to be reasserted in a good many instances, where parents regarded it as another unlikely story.

Complaints about National bread as a cause of childhood troubles bore a definite political distribution, and complaints about housing, with more foundation, were adduced in most cases of respiratory trouble.

The clinics were used largely as a source of health teaching, by posters, films, and admonition ; and clothing, foods, pamphlets, and demonstrations were shown by the health visitors, generally with good result.

WEAKNESSES

Our main weakness was probably our fragmentary attitude to the family. Since it is not practicable to see at such a clinic more than the mother and one or perhaps two children of about the same age, treatment of the kind we could give lacks a proper diagnostic basis. The family is an ecological unit. If we could have supervised the entire group on Peckham lines, or enjoyed the same facilities as the family doctor, we could have done more. In most cases, throughout all income groups, we found that the practitioner or, more often, practitioners, were used more as one employs a plumber than as family consultants. War and migration had so largely destroyed the family unit of practice that we were constantly called to integrate treatment where mother, children, and father were attended severally (and, it appeared, in strict secrecy) by separate doctors and by two or three hospitals, and our clinics were added to the collection of opinions

published series of hospital cases is in part the product of non-notification, designed to avoid the "stigma" of tuberculosis, which leads to non-detection of contacts and to the return of the sensitised child to an infected milieu. The most serious obstacle to the work of both the clinics and the tuberculosis officers seemed to be the slowness with which patients could be placed in sanatoria; so patients with plainly active tuberculosis were sometimes referred by us directly to general hospitals.

The disposal of patients with other diseases raised unanticipated problems of professional conduct. Most of the patients already attended private practitioners, and, where possible, defects were referred to them; but the impossibility of securing a follow-up, combined with the attitude of certain patients who did not let us know that they were already under treatment, complicated the issue. There was a strong tendency for patients to use the clinics to check their own doctor's treatment and to get to hospital in spite of his advice; we did our best, when we detected this, to discourage it. The full coöperation of most local doctors did not always save us from invidious decisions, and we ended by referring directly to voluntary hospitals most cases requiring treatment. This was defensible, in our view, only because of the peculiar position which such clinics, publicly financed and publicly canvassed, must needs occupy, and we make no claim to have solved fully or satisfactorily the problems of cooperation with the general medical services outside the borough scheme—the blame, if any, rests not on the practitioners but on the inherent difficulties of any dual system.

We never advised tonsillectomy or other surgical treatment directly; we referred all cases which might require it for a surgical opinion. Dental treatment and eye refractions were undertaken through the L.C.C. minor-ailments scheme. All cases of ankle-weakness and knock-knee severe enough to need treatment and all cases of speech defect were referred to a voluntary hospital. The clinics accordingly functioned as a clearing-house and advisory centre, especially the latter.

ptoms Complained of

norexia in only children probably heads the list of plaints; and here we made much use of the leaflet ed by the National Council for Health Education. istent cough, dating from measles or an infection, e second, the cases falling fairly definitely into a llar group, an allergic group, and a "mixed bag," ng the severer members of which we searched ematically for latent bronchiectasis, and of these suspect cases passed out of our hands for broncho- phy and other investigation.

he third major group was psychological: enuresis, which parental reactions seem to be much improved; or; minor disorders of behaviour; and "nervous- s." There was no great incidence of unmanageability age-group was not suitable for conclusions on "delin- nt" reactions, and the period of exposure to parental rosis had been from birth to early childhood, not n early childhood to prepuberty). Nervousness and chogenic troubles were almost uniformly attributed parents to prenatal trauma by bombs, and equally uniformly traceable to parental neurosis, of which obsessional manifestations did, on the whole, most damage and anxiety states made up the major part. In two cases we sent the children for "guidance"—in all the others requiring treatment we referred the parents directly to the psychiatrist.

Parental neurosis proved to be our most contagious disease, and one to which children possessed no resistance whatever. Its incidence is by far the highest in the better educated family group. Some of the happiest and healthiest of our children were adopted, chiefly in working homes. Of the causes of parental trouble, conscription and its effects came first and lack of sexual and contraceptive knowledge second, followed closely by housing deficiencies. Economic fears were not significantly represented. The clinics spent as much time on minor psychiatry as on all the other activities put together. Even in the children who remained in London, bombing, as an experience, did far less damage than tonsillectomy or brusque treatment in hospital, a point which must be borne in mind when surgery is being considered.

Ignorance and Error

Parental education varied, and health knowledge (and superstition) with it. It is of more social than medical interest, perhaps, that over three-quarters of mothers "touched wood" when asked for details of past infection. This xylolatry, as it might be called, was general among unbelievers in immunisation.

Two of our chief enemies were proprietary infant powders and camphorated-oil rubs, the first as a cause of obstinate bowel atony, and the second as a source of macules, papules, and pustules.

The campaign for vitamins has produced more zeal than instruction, and a good many mothers are ready to substitute for the official concentrates not only fortified infant foods and "body-builders" but also unfortified iron tonics, irrespective of whether vitamins are being received from other sources.

Most cases of intolerance to cod-liver oil were due to management, but a few were genuine fat-intolerance, and there was a definite incidence of allergic responses to orange-juice.

Castor oil still figures occasionally as a weekly dose for young children, and as a specific for bellyache, and the prevalence of enemas for oxyuriasis continues, with some professional backing. It had usually caused more trouble in our cases than the parasites, and parental good sense terminated treatment in most cases.

So many superstitions have been attacked by hygiene teaching that the relation between stammer and left-handedness needed to be reasserted in a good many instances, where parents regarded it as another unlikely story.

Complaints about National bread as a cause of childhood troubles bore a definite political distribution, and complaints about housing, with more foundation, were adduced in most cases of respiratory trouble.

The clinics were used largely as a source of health teaching, by posters, films, and admonition; and clothing, foods, pamphlets, and demonstrations were shown by the health visitors, generally with good result.

WEAKNESSES

Our main weakness was probably our fragmentary attitude to the family. Since it is not practicable to see at such a clinic more than the mother and one or perhaps two children of about the same age, treatment of the kind we could give lacks a proper diagnostic basis. The family is an ecological unit. If we could have supervised the entire group on Peckham lines, or enjoyed the same facilities as the family doctor, we could have done more. In most cases, throughout all income groups, we found that the practitioner or, more often, practitioners, were used more as one employs a plumber than as family consultants. War and migration had so largely destroyed the family unit of practice that we were constantly called to integrate treatment where mother, children, and father were attended severally (and, it appeared, in strict secrecy) by separate doctors and by two or three hospitals, and our clinics were added to the collection of opinions

published series of hospital cases is in part the product of non-notification, designed to avoid the "stigma" of tuberculosis, which leads to non-detection of contacts and to the return of the sensitised child to an infected milieu. The most serious obstacle to the work of both the clinics and the tuberculosis officers seemed to be the slowness with which patients could be placed in sanatoria; so patients with plainly active tuberculosis were sometimes referred by us directly to general hospitals.

The disposal of patients with other diseases raised unanticipated problems of professional conduct. Most of the patients already attended private practitioners, and, where possible, defects were referred to them; but the impossibility of securing a follow-up, combined with the attitude of certain patients who did not let us know that they were already under treatment, complicated the issue. There was a strong tendency for patients to use the clinics to check their own doctor's treatment and to get to hospital in spite of his advice; we did our best, when we detected this, to discourage it. The full coöperation of most local doctors did not always save us from invidious decisions, and we ended by referring directly to voluntary hospitals most cases requiring treatment. This was defensible, in our view, only because of the peculiar position which such clinics, publicly financed and publicly canvassed, must needs occupy, and we make no claim to have solved fully or satisfactorily the problems of coöperation with the general medical services outside the borough scheme—the blame, if any, rests not on the practitioners but on the inherent difficulties of any dual system.

We never advised tonsillectomy or other surgical treatment directly; we referred all cases which might require it for a surgical opinion. Dental treatment and eye refractions were undertaken through the L.C.C. minor-ailments scheme. All cases of ankle-weakness and knock-knee severe enough to need treatment and all cases of speech defect were referred to a voluntary hospital. The clinics accordingly functioned as a clearing-house and advisory centre, especially the latter.

Distribution of Drugs and Supplements

The clinics also acted as distributing centres for Ministry of Food supplements and dietetic extras provided through the borough. Complaints of poor tolerance were investigated and, where reasonable, capsules and concentrates substituted for Government oil, and other sources of vitamin C for orange-juice. The acceptance of these by the public was uniformly good, though the higher income-groups preferred dear proprietaries of low antirachitic value to free or cheap cod-liver oil.

The cases showing active or recent rickets were few. Our criteria (not usually confirmed by radiography) were those given by Hamilton et al.[1] (delayed dentition, hypotonia, head-sweating, and delayed walking), since our purpose was prevention rather than investigation. The remark about injection at clinics applies to the investigation of vitamin-C deficiencies; in a private series of similar range it would have been possible to use Slobody's intradermal tests on a mass scale, but this would have destroyed the other and more valuable work of the clinics.

Scope of Work

We found limitation of the effective scope of work undertaken in the clinic to be one of the prime conditions of success. In planning this scope we estimated that a maximum of 15 cases would be seen in a session of two hours, allowing for the shorter time occupied in dealing with return visits. To derive the greatest value from the time at our disposal, we needed to adopt a very different approach from that of the diagnostician in or out of hospital, who conducts the treatment but ceases to supervise the case as normality is restored. We had to deal with and prevention, particularly with the forest conditions likely to need surgery; and, though data were collected, we did not pursue data for own sake: we did not, for instance, control all of suspected rickets by X rays or chemistry—not indiscriminate dosing with supplements has any cation, but because of the importance of deficiency on one hand and sparing the parent on other. So long as hospital attendance involves a which in many cases exceeded six hours from the lished time of the clinic (cases where patients at 9 A.M. for a short consultation or investigation not seen until late afternoon were common, hospitals of national standing in pædiatrics), the control of supplements must wait until there are facilities for investigation in the health-centre. We relied chiefly on hospitals which had insti appointment system. Apart from this fact, we a principle to devote time rather to advising the of normal children on general and minor problems to giving special advice where patients were fo be clinically ill.

The system of fixed "skeleton" case-taking dir at the commonest undetected or symptomless ab malities, with immediate reference back of cases, as as provisionally diagnosed, for treatment and inves tion elsewhere, suited the function for which the c were designed. In all cases the reports of other in tions were filed in our records and we resumed superv of the case at the point where it was discharged specialist care.

FINDINGS

Higher wages, evacuation, and the bombing of Government supplements to diet, and improved education have borne remarkable fruit in the phy state of London children. At the same time conscrip the universal cheapening of human responsibility, small family, gross housing deficiencies (especially attempt to rear children in flats), and the fraying parental nerves through shortages and enforced deprivation have contributed a psychological balance.

Rickets.—Out of some 2500 children examined not than 24 were on clinical findings grossly rachitic, th perhaps 100 needed greatly improved nutrition, and a centage showing clear evidence of neglect hinted at existence of other neglected children whose parents unlikely to bring them voluntarily to attend at clinics.

Tuberculosis, where Vollmer reversal took place under eyes, was generally traceable to a close home contact or visit to the country. Our results were another proof of value of routine child tests in detecting adult disease.

Weights and heights compared favourably with figures. The most salient deficiencies were all minor; extreme disorganisation of war made this a very vaccinated population (less than 50%), though reached 90% in some clinic zones and refusals in the group were uncommon. We have deliberately ex tables, since the voluntary character of the attendance it important that our figures should not be taken as an sample.

Scabies was very rare; *pediculosis* moderately common.

Dental caries tended to appear in 30% of cases about third year, and predominantly affected the incisors. C were divided into those where defective enamel-form led to incisor caries at gum-level, those showing symm first-molar cavities, and those showing both. *Parents* perhaps least coöperative in accepting conservative on deciduous teeth, even when dentists had declined extract and explained the reasons for the decision. instances of striking neglect were found in otherwise inte families, one child having five active and palpable ab

Phimosis.—The many cases of avoidable phimosis children who had not attended infant-welfare clinics

trongly that better instruction by maternity hospitals ily practitioners would save the children from needless

Routine examination of the genitalia should be f every pædiatric examination of boys, and mothers e specifically instructed in their care. It would be ng to know how phimosis terminates if left to itself— primitive peoples who do not practise circumcision. experience every prepuce which is not regularly l to becomes adherent.

l Coöperation

standard of parental coöperation was high, even he voluntary attendance is taken into considera- he mothers with whom we had to deal had been ed to various external and internal stresses: but, er deterioration has taken place in the environ- f the family, some of the fruit of pre-war psycho- and hygienic instruction is fairly obvious in our nce. Sanity of attitude toward enuresis, mastur- jealousies in the family, and the conception of ne is largely an outcome of such past teaching. , we found evidence to support the view put for- y Halliday that future effort in advisory clinics needed to counteract over-enthusiastic ideas of a rather than to instil new ones.

ssional patterns in mothers thwarted over the habit or appetite of their children are certainly nest in the intelligent and the hygienically l. We often conducted propaganda for rather more y dirt, constipation, and anorexia. "I've kept his pot for two hours, he's that stubborn," is a ark in the deformation of a personality, though in ses the child generally won. We shall have to see he decay of a coercive morality does not leave for the growth of an equally coercive and irrational f the time-table in childhood. The danger is sed in circumstances where pre-school children t flats in ones or two's, without safe facilities for unal play. The higher physical standard of housing se flats is more than offset by the consequences e child.

y Planning

encountered much spontaneous comment on the rate problem in reply to the question "How many en?" The reasons adduced for limiting the family strikingly uniform, war coming first, fear of renewed econd, and the consequences of war, particularly ng, third, followed by economic considerations. hey want us to have children, they can stop our eaking"; "It's no world for children, we think"; d time" and health reasons were not common, and h proportion of women with a rheumatic heart three or more children by choice in the face of appreciation of the physical result.

ptoms Complained of

orexia in only children probably heads the list of plaints; and here we made much use of the leaflet d by the National Council for Health Education. istent cough, dating from measles or an infection, e second, the cases falling fairly definitely into a illar group, an allergic group, and a "mixed bag," ng the severer members of which we searched ematically for latent bronchiectasis, and of these suspect cases passed out of our hands for broncho- phy and other investigation.

he third major group was psychological: enuresis, which parental reactions seem to be much improved; or; minor disorders of behaviour; and "nervous- s." The clinics were used largely as a source of health teaching, by posters, films, and admonition; and clothing, foods, pamphlets, and demonstrations were shown by the health visitors, generally with good result.

WEAKNESSES

Our main weakness was probably our fragmentary attitude to the family. Since it is not practicable to see at such a clinic more than the mother and one or perhaps two children of about the same age, treatment of the kind we could give lacks a proper diagnostic basis. The family is an ecological unit. If we could have supervised the entire group on Peckham lines, or enjoyed the same facilities as the family doctor, we could have done more. In most cases, throughout all income groups, we found that the practitioner or, more often, practitioners, were used more as one employs a plumber than as family consultants. War and migration had so largely destroyed the family unit of practice that we were constantly called to integrate treatment where mother, children, and father were attended severally (and, it appeared, in strict secrecy) by separate doctors and by two or three hospitals, and our clinics were added to the collection of opinions

whenever we failed to forestall it. The patient who goes to Dr. X with her feet and Dr. Y with her head, and takes the medicine, often identical, of both is a force to be reckoned with. One child was receiving three separate supplies of phenobarbital for her non-epileptic seizures. Coupled with this are the "welfare mentality" and the perpetual "scrounging" for certificates that goes with it.

Another limitation on our work was the extreme load placed on health visitors by the combination of statutory and supererogatory obligations, which they met with much good will, but which restricted the amount of following-up which we felt justified in ordering.

CONCLUSIONS

Voluntary attendance for treatment must be the basis of all ethical practice in any medical service, and zeal for public health should not lead to any further over-persuasion, "snooping," or invasion of privacy. In the present sociological conditions we are powerless to reach, by the system of welfare described, the "bad" cases; but evidence suggests forcibly that coercion, particularly imprisonment for neglect, without re-education is equally impotent.

The chief lesson brought home to us by these clinics is the need for an increasing autonomy of such services in the hands of the attending public, the substitution of coöperation for supervision. A second is the unproductivity of palliative activities in the context of what Mumford termed *megalopolitanism*.

From the more immediate angle of administration, closer liaison with the local practitioners, hindered now by their lack of time for anything but their growing burden of work, and with such agencies as marriage-guidance and psychiatric clinics and care committees comes first among our immediate suggestions.

The numerous limiting-factors which affect our findings make them hard to compare with existing and known findings in America, under the partial State scheme in Sweden, and in pre-war England. For this reason we have not produced numerical statistics.

My thanks are due to Dr. H. W. Barnes, medical officer of health for Camberwell, for his kind permission to publish these comments, and for his unflagging interest and guidance in the affairs of the clinics; the health visitors of the borough for their predominant share in the work done; and the parents for their consistently intelligent coöperation. The opinions expressed in this article are the sole responsibility of the writer and are not necessarily endorsed or shared by the public-health committee, the medical officer of health, or any other officer or officers of the Camberwell Borough Council.

The June Quarter

According to the Registrar-General's return [1] 235,037 births were registered in England and Wales during the quarter ended June 30, representing a birth-rate of 22·0 per 1000 population. This is the largest number of births recorded for any June quarter since 1920. For the March quarter of this year, however, the figure was 241,421 with a rate of 22·8; and the June quarter is the first since that of March, 1946, to show a drop on the previous three months. Illegitimate births accounted for 5·4% of the total births, compared with 7·3% in the same period of 1946.

A Social Survey report accompanying the return shows that, of those interviewed, 69·6% had an illness or injury during the three months January, February, and March, 1947. There was an average monthly loss of 1·6 days for all persons interviewed, and an average of 32 consultations for every hundred illnesses recorded.

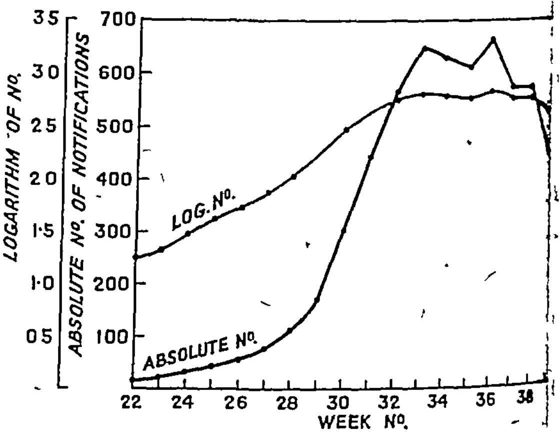
Domestic Drainage

The report of a study [2] undertaken by a committee of the Building Research Board for the Ministry of Works is to be recommended to medical officers of health well as to builders and surveyors; for domestic dr are the source of many public-health nuisances.

The common defects in domestic drainage, listed the first part of the report, range from general de pipe sizes and gradients to the materials used and absence of record plans for the location of pipes. T recommendations made in part II to meet these def are illustrated by a specimen lay-out, and the third p deals with materials and construction. Here the to experiment with new materials is stressed, and spe mention is made of a bituminised-fibre drain and pipe which has been used with success in Canada America. By means of driven tapered collars these p can be jointed as fast as they are lowered in to the tre

Poliomyelitis

The number of notifications of poliomyelitis in En and Wales in the week ended Sept. 27 was 441 and of polioencephalitis 32 (23). The figures fo previous week are shown in parentheses. Thus was a fall of 130 *in notifications of poliomyelitis*— greatest fall since the epidemic began. Both in 1 and in 1926, when there was a high prevalence, fa incidence occurred in September but were followed increases in early October. It is therefore too early assume that the curve of incidence is permanently the down-grade, though the fact that the high incide



started early may be some justification for hoping th the decline may come early also.

The decline in London continued, with 30 cases co *pared* with the previous week's 53, but figures admissions to London hospitals since Sept. 27 sugg that the fall may not be so great when the next wee figures become available. Most of the counties sho a fall, the principal exceptions being Bedford 6 Cheshire 15 (11), Lincs (Lindsey) 16 (8), and Carmart 6 (2). The general picture is one of some decli perhaps a little more noticeable in the south than in th north.

Infectious Disease in England and Wales

WEEK ENDED SEPT. 27

Notifications.—Smallpox, 0; scarlet fever, 58 whooping-cough, 1105; diphtheria, 184; paratyph 10; typhoid, 22; measles (excluding rubella), 11 pneumonia (primary or influenzal), 257; cerebrospi fever, 30; poliomyelitis, 441; polioencephalitis, 3 encephalitis lethargica, 2; dysentery, 87; puerpe pyrexia, 104; ophthalmia neonatorum, 44. No ca of cholera, plague, or typhus was notified during th week.

Deaths.—In 126 great towns there was 1 (0) dea from enteric fever, 1 (0) from scarlet fever, 1 (0) fro measles, 3 (0) from diphtheria, 6 (0) from whooping cough, 87 (5) from diarrhœa and enteritis under t years, and 2 (0) from influenza. The figures in parenthe are those for London itself.

The number of stillbirths notified during the wee was 222 (corresponding to a rate of 25 per thousa total births), including 30 in London.

In England Now

Running Commentary by Peripatetic Correspondents

HERE in Lhasa I am again encountering the autumn of P.U.O. Last year it became sufficiently prevalent attract official Tibetan notice and this year for sons which will be explained later some of the large ial families are agreeing to T.A.B. inoculation.

n Tibet P.U.O. comprises three diseases—enteric, hus, and relapsing fevers. My excellent microscope kes the diagnosis of the last an easy matter; but hout facilities for bacterial culture or serum agglutation the differentiation on clinical grounds of the t two is difficult, if not impossible. Thanks to the dness of the Calcutta School of Tropical Medicine I e had a number of representative sera agglutinated; bias is in favour of enteric. On clinical and public-lth grounds too, enteric seems the more likely. What total figures in Lhasa are and how many households affected I have no means of ascertaining. But the l must be high.

betan medicine, sponsored by the government, tly consists of the administration of mixtures of bal and religious powders based on the writings of ents some 600 years old. It is quite static. The y semblance of a health service lies in the fact that government sends one of their own monk doctors h important officials posted out in the blue. But of these whom I tried to train was incapable of ng a syringe and seemed much more interested in pressing us with his quack knowledge than in soiling hands doing simple dressings. Anyway I suppose official derives a certain mental comfort from ing a "doctor" capable of administering useless ders.

hen a Tibetan falls ill he seeks the advice of an arnate lama. The lama, who often does not even the patient, may advise intensive religious ceremonies considerable gain to his fraternity); he may say a etan doctor can cure the patient: or he may suggest ing the "British doctor." But prejudice and ignonce die hard (hardest in Tibet) and it is only the more ightened lamas or those known to me personally o dare direct patients to me with any frequency. result is a hard core of untreated disease, a vast ount of preventable suffering, and a staggering fantile mortality.

For some months past an uncomfortable number of nks have been dying in the largest monastery in the rld. Drepung, with its 7700 monks, seven miles from asa, is far too reactionary to welcome the attentions investigations of the British doctor. What the idemic is I can only guess from what is happening ewhere. The present interest of this lies in the fact at it is in Drepung that the young Dalai Lama, now years of age, will shortly stay for a month surrounded the entire Tibetan hierarchy. And these officials are ared of the epidemic. They turn to me for advice. o use confessing to them one's indecision about the ture of the disease. No; much better to get them otected against the disease prevailing elsewhere and n into their heads some of the rudiments of its prevenon. And perhaps the appropriate star having duly ppeared in the heavens and permitted the start of the ficial bathing season, the louse population will be duced and the relative percentage of enteric thereby creased.

* * *

I have been chastened, though I am glad to say I did ot have to beat my breast and cry "*Mea culpa!*" t a party lately an official from a N.H.I. pricing bureau, earning that I was a physician, opened on me with such weight of armament that I gulped a cocktail more than had intended. While most of our profession were eers among men, did I realise (he asked) that there were .B.'s and even M.D.'s whose prescriptions were a hissing nd a reproach through the whole of the pharmaceutical rofession? No? Well, for a start there was the doctor ho commonly signs his name in the middle of his rescription forms. One puzzled pharmacist interpreted is signature as "Catheter lubricant ℥ iv" and supplied this along with the barbiturate which was prescribed. Whether the patient took the oil nocte s.o.s. is not recorded.

There were too many occasions when illegible writing drove frenzied pharmacists to a calming snifter of bromide. But the pharmacist did his best, and doctors disliked telephoned requests to decipher their scripts. So "EMCLO," a doctor's own graphalog for extract of malt and cod-liver oil, was turned into tinct. codeinæ ("Goodness," I murmured, "what about the dose?" but the attack swept on). One order intended for "Tab. multivite 48" was translated as Ung. zinci ℥ iv *and another was read as* phenobarbitone; the prescription "Ung. hydrarg. ℥ vi" Sig. ℥ i t.i.d., p.c. was undoubtedly a slip corrected by telephone. And why did some medicos still insist on using the old *National Formulary* or even the one before that? The third edition of the *N(W)F* was now issued to every practitioner and there was no excuse for using any other.

The pharmacist paused for breath, so I announced firmly, "I am now going to do some prescribing myself. *Recipe: Spiritus juniperi, syrupi limonis, aquæ glacialis, quantum sufficiat. Misce secundum artem. Phiala prius agitata repetatur.*" We parted on amiable terms.

* * *

The everyday feats of Indian classical dancers would baffle the anatomists. Many of their dances start with a series of lateral movements of the head, without rotation in any plane. This seems to be an arthrological impossibility. Then, with arms outstretched, a rippling wave starts at the finger-tips of one hand, passes up the forearm and arm, across the shoulders, and down the arm and forearm to the finger-tips of the other hand. Try these two movements in front of your bedroom mirror, and you will not be surprised to learn that the training of an Indian dancer takes twelve years.

These reflections were prompted by the demonstration of his superb art by Ram Gopal at the reopening ceremony of the Indian Section of the Victoria and Albert Museum. An Indian classical dancer has to learn many thousands of traditional stylised movements, each one of which has a particular meaning. Every limb has its own catalogue of movements; the number of facial expressions runs into thousands and there are five thousand separate gestures of the hands. These are all learned early in the dancer's training, and later they are blended into dances. A dance is thus full of meaning; every gesture and expression, however slight, has a definite significance and is as much an organic part of the whole as is every phrase uttered by every instrument in an orchestral piece.

It follows that Indian classical dancing is a most difficult and exacting discipline. Every movement is precisely regulated; an extraneous gesture, an inaccurate facial expression, an unintentional flourish may alter the whole meaning of a dance. And yet, Ram Gopal and his pupils appear to be free and spontaneous in their movements. Dancing to simple rhythms, they blend their gestures into a flowing and profoundly beautiful work of art.

* * *

I think I'll give up psychosomatic diagnosis for a bit. When my oldest, and recently married, friend began to complain of listlessness, depression, and nausea I questioned him on personal and private matters with the guile of a serpent. When it was revealed that his mother-in-law was resident and helping her daughter to settle in, things seemed to be getting warm. When he confided to me that his sickness always came on just before having to confront her at the breakfast table, I felt myself to be probing with the skill of a Freud and Harvey Cushing combined. Beaming, I condescendingly explained the interrelations of psyche and soma, prescribed a little tonic and rather more alcohol, and urged the rapid removal of ma-in-law. Three days later, when I was on holiday in the wilds of Essex, my friend put through a trunk call to tell me that jaundice had set in and what should he do now please? He may have turned yellow but, as our American friends say so aptly, was my face red?

Letters to the Editor

GASTRIC HYPERSECRETION WITH DUODENAL ULCERATION

SIR,—There appears to be no generally accepted explanation of the gastric hypersecretion which is frequently associated with duodenal ulcer. On simple theoretical grounds it seems that three hypotheses must be considered: (1) that the humoral stimulating mechanism is hyperactive; (2) that the nervous stimulating mechanism is hyperactive; and (3) that the glands of the stomach are hyperresponsive.

The last two hypotheses are susceptible to test. If the gastric hypersecretion associated with duodenal ulcers were due to a hyperreactive stomach, it might be expected that in such cases histamine, which excites the secretory mechanism even in the absence of the extrinsic, nerve supply, would give rise to an exaggerated secretory response as compared with that of normal subjects. On the other hand, if the cephalic centre were hypersensitive, it might be expected that the gastric secretory response to a fall in blood-sugar after the intravenous injection of insulin would be greater in patients with duodenal ulcers than in normal subjects.

TABLE I—SECRETION OF CL$^-$ IN THE HUMAN STOMACH AFTER STIMULATION WITH HISTAMINE AND INSULIN

Group of subjects	No. of subjects	Mean secretion (Cl$^-$/hr. milli-equiv.)		$\frac{I}{H}$
		After histamine (H)	After insulin (I)	
Normal ..	24	16·11(±1·25)	21·62(±1·54)	1·34(±0·14)
Duodenal ulcers..	19	24·81(±2·00)	27·92(±2·27)	1·12(±0·14)
Gastric ulcers..	20	14·75(±1·97)	20 19(±2·58)	1·37(±0·25)

Standard errors are shown in parentheses.

The published figures of Ihre,[1] who performed successive histamine and insulin tests on normal subjects and patients with gastric and duodenal ulcers, allow these two hypotheses to be tested without further experimental work. For details of the criteria adopted in the selection of his normal and pathological material, Ihre's admirable treatise should be consulted. I have made a statistical analysis of the total amounts of chloride and pepsin secreted in one hour by his subjects. This has allowed a clearer appreciation of the differences between groups than can be obtained from the graphical presentation adopted by Ihre.

TABLE II—SECRETION OF PEPSIN IN THE HUMAN STOMACH AFTER STIMULATION WITH HISTAMINE AND INSULIN

Group of subjects	No. of subjects	Mean secretion pepsin (units/hr.)		$\frac{I}{H}$
		After histamine (H)	After insulin (I)	
Normal ..	24	3453(±309)	7639(±730)	2·21(±0·29)
Duodenal ulcers..	19	5372(±401)	13090(±1460)	2·43(±0·40)
Gastric ulcers..	20	3372(±487)	8790(±1115)	2 61(±0·50)

From table I it may be seen that the secretion of chloride in response to histamine stimulation was of the same order in normal subjects and patients with gastric ulcers. The patients with duodenal ulcers secreted a mean of 54% (standard error of mean 15%) more than the normal group. This difference is significant since it is more than three times its own standard error.

It may be seen from table II that similar differences exist between the groups for the secretion of pepsin in response to histamine. The cases of duodenal ulcer secreted a mean of 56% (standard error of mea more pepsin than the normal group. Thus the to histamine is about 55% more than normal chloride and pepsin are considered together assessment is of value in interpreting the results o with insulin.

The magnitude of the gastric secretory respon lowered blood-sugar depends on at least two f the response of the cephalic centre and the ability stomach to reflect vagal activity by its secreti the stomach is incapable of secretory activity the test can give no indication of the reaction of the centre; on the other hand, if the peripheral se mechanism of the stomach is hyperreactive, re weak stimulation from the vagal centre may g to hypersecretion. However, the response to h may be used to assess the state of the peripheral s mechanism. The ratios in the last column deemed to represent the activity of the vagal con of the secretory mechanism, the variations in pe sensitivity having been eliminated by divid figures for the response to insulin by the sensitivit peripheral mechanism as assessed by the to histamine. Thus the larger the value of th the more active is the vagal centre. It may from the figures that there is no significant di between the activity of the vagal centres in th groups as revealed by the figures for chloride or

Thus it may be concluded that the peripheral s mechanism is hyperreactive in those cases of d ulcer showing gastric hypersecretion, and that hypersensitivity of the cephalic centre cannot be e by these experiments, there is no evidence to such a hypothesis.

This interpretation of these experiments might as evidence against the value of vagotomy in duodenal ulcer with hypersecretion; but recent have indicated that the secretory response of the to histamine is considerably reduced after va The successful results of vagotomy thus do not against the hypothesis of the peripheral origin gastric hypersecretion associated with duodenal

Guy's Hospital, London, S.E.1.

SECOND ATTACKS OF POLIOMYELIT

SIR,—Many practitioners I meet hold the vi one attack of poliomyelitis practically preclu possibility of a second, with the result that when attack does occur the diagnosis is apt to be del missed. Three officers belonging to different un attacked with poliomyelitis at Deolali, India, and May, 1947. One of them gave a clear histo another an almost certain history, of a previous of the disease.

CASE 1.—In 1938 the patient and his brother ha attacks of poliomyelitis during an outbreak at a school. In his case the brunt of the paralysis fel muscle-groups of the legs; recovery was rapid and fu was regained in six months. He served as an office the war.

On May 7 of this year the patient, now aged 27, was with fever and pain in the back and right leg. On weakness developed in the left leg. On the 9th the left girdle became affected and there was transient twitchi left lip. Fever lasted till May 16, by which time p begun to return in the left shoulder and right leg. On there was full power in the left shoulder, moderat power (grade 4) in the right quadriceps and ha weakness (grade 3) in quadriceps, hamstrings, ante posterior tibial groups in the left lower limb, and lo knee- and ankle-jerks. There was no sensory abnorm

CASE 2.—An officer cadet, aged 20, was admitte pital at Bangalore, India, on Dec. 27, 1946, from an training school during an epidemic of poliomyelit He had fever, photophobia, backache, stiffness a rigidity of the neck, and congestion of the fauces was no paralysis but the left biceps-jerk was absen cerebrospinal fluid contained 15 cells per c.mm. pressure was 140 mm. of water. Poliomyelitis was d and he was five weeks in hospital.

[2] Grimson, K. S., Baylin, G. J., Taylor, H. M., Hesse Rundes, R. W. *J. Amer. med. Ass.* 1947, 134, 925.

n May 13, 1947, at Deolali, some 500 miles from Bangalore, egan to be feverish. On the 14th he had headache and ache, and he vomited. On the 15th the eyes were ted, the mouth was twitching, and he was obviously ill. the morning of the 16th his condition rapidly became e. He was cyanosed, cold, and clammy; the pulse was d and feeble; he could not swallow or cough and food was rgitated. Movements of the chest were poor and all s were weak. There were continual twitching move- ts of the face, arms, and legs. The pharyngeal reflexes sluggish, and knee- and ankle-jerks were absent. ation was unimpaired. He died at 10 A.M.

istological examination of the brain showed, in sections the medulla oblongata, extensive diffuse microglial pro- tion with œdema of the affected areas and obvious nerve-damage, intense perivascular cuffing of the blood-vessels lymphocytes, and moderate lymphocytic infiltration in meninges The cerebral cortex was normal and no ological changes, especially no Négri bodies, were ted in the cerebellum. No evidence of old lesions of myelitis was seen in the brain: the spinal cord, which d have been more likely to show them, was, unfortunately, ent for examination.

e third case at Deolali occurred on April 17 of this . It was a typical attack with extensive paralysis e lower limbs.

m indebted to Lieut.-General T. O. Thompson, director dical Services, for permission to send this letter; to -Colonel C. W. Greenway, R.A.M.C., Lieut.-Colonel Walters, late I.M.S., and Capt. J. L. Edmondson, R.A.M.C., otes of the cases: and to Major L. Kramer, R.A.M.C., e histopathological report.

AILURES IN CORTICAL BONE-GRAFTING

R.—I have only now had the opportunity of seeing aluable paper by Ellis, Langston, and Ellis (July 26). his and another orthopædic centre our experience fully borne out the remarks made by these authors. cases were almost entirely of gunshot wounds with e bone loss. The final analysis will show therefore her percentage of operations—probably about 20%. se 6 interested me particularly as we have seen al like it: the graft incorporates well, but the actual ure unites poorly or, it is suspected, not at all. It s that the rigid fixation afforded by the graft elimi- s the important factor of longitudinal compression. over one cannot "slot" the screw holes in the graft out weakening it to the extent of risking a fracture. danger can, however, be overcome with plates. me degree this compressing force was obtained in the wing way.

e femur and tibia pin traction was applied. For the r extremity manual traction was used. After freshening one ends a disk of cancellous bone, cut from the iliac , was laid between them. Traction was released, and the was firmly compressed between the fragments. The onlay then secured in the usual way. Latterly, plate fixation was used where the gap was not extensive. Further llous chips were packed around the site. The amount of visible radiologically after three months, especially in emur, is surprising. Lately the cortical graft has been very infrequently, except where the gap was 2 in. or Reliance has been placed on plate fixation and large massive iliac-crest grafts. In one case this method was for a fracture of the upper third of the tibia. In spite of , admittedly not severe, union took place in eight ths. Penicillin has been in routine use.

was our impression that the problems of nutrition fixation could be best met by the use of massive grafts and plates. I have no doubt that this com- sion method of securing a cortical disk is in use where. A further advantage is that the iliac graft is y cut and shaped, and consent to its removal is e easily obtained than to the removal of bone from sound leg.

hile the use of the living cancellous graft with plate ion seems to answer points (2) to (5) of the paper red to, sepsis remains as the outstanding factor. nique, judgment as to when to operate, and the use of penicillin provide some of the answers to the problem of sepsis. In any event, its occurrence does not seem to be so disastrous when cancellous grafts are used.

Military Hospital, Jalahalli, Bangalore. T. DENNESS.

ACTION OF MEPACRINE ON GASTRIC SECRETION

SIR,—The most promising developments in the treatment of peptic ulcer at the moment are the methods of inhibiting the secretion of that fraction of the gastric juice dependent on vagal stimulation, whose continued production is held to be an important factor in this condition. It has recently been reported[1] that in dogs mepacrine strongly inhibits this secretion. The following observations were made to discover whether a similar effect could be obtained in man.

The patients were males undergoing gastric investigation for various reasons. Vagal secretion was provoked by the intravenous injection of 16 units of insulin, the hypoglycæmia being recorded by simultaneous blood-sugar estimations. All cases showed an adequate fall of blood-sugar level, together with the usual symptoms of restlessness and sweating. Gastric contents were removed by continuous aspiration for 15 min. before the injection and five 15-min. periods afterwards. The procedure was then repeated with 400 mg. of mepacrine injected intravenously at the same time as the insulin.

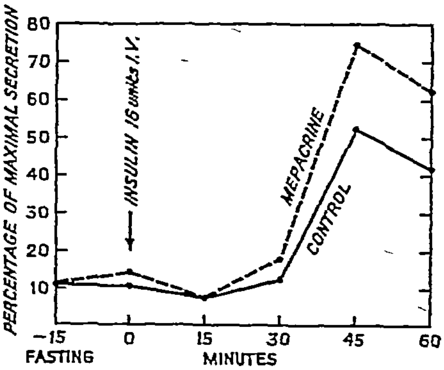

Fig. 1—Graph of secretion of gastric juice after intravenous injection of insulin, showing that simultaneous injection of mepacrine does not inhibit secretion: graphs are average results in four persons with and without mepacrine.

The results in four typical cases are summarised in fig. 1, in which the total acid secretion (volume × acidity) for each period has been expressed as a percentage of the maximum for that patient, and the average of the four percentages recorded. It will be seen that no inhibition is produced. Fig. 2 shows the results in the only case in which an inhibitory effect was obtained, where it was part of a well-marked toxic reaction to mepacrine. This took the form of nausea and abdominal pain for about six hours, followed by vomiting. A test dose of 100 mg. by mouth, as given to each patient, had not given rise to any discomfort.

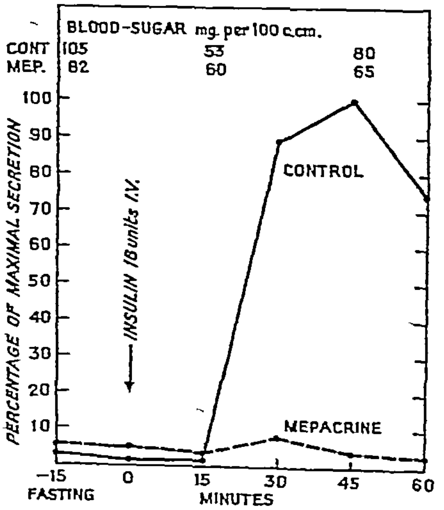

Fig. 2—Graph of secretion of gastric juice showing inhibition of secretion in a patient in whom mepacrine produced a toxic reaction.

---

[1] Babkin, B. P., Karp, D. *Canad. med. Ass. J.* 1947, 56, 137.

The failure to produce the inhibitory effect observed in dogs may be due to the fact that the doses used in animal experiments were relatively much greater—i.e., about 10 mg. per kg. of body-weight, or 700 mg. for a 10-st. patient, which is outside the ordinary safe therapeutic range.

My thanks are due to Dr. W. I. Card for his advice in planning this experiment.

Cheam, Surrey. C. P. PETCH.

MORE STONES FOR OUR GLASS HOUSE

SIR,—Dr. Marshall tells us in his letter (Sept. 20) that the *Pocket Oxford Dictionary* defines micturition as "(A morbid frequency in) passing urine." *The Shorter Oxford Dictionary* goes further. Omitting the saving brackets it says: "The desire to make water; a morbid frequency in the voiding of urine." Then, as if to clinch the matter, it adds: "Often erron.: The action of making water." But the last, which is the usual, is also really the correct meaning.

The compilers of the dictionary have evidently been misled by the derivation from micturio. It is true that in classical Latin this verb would have the meaning "I desire to make water," but in actual fact it does not exist in classical Latin at all but is found in the *sermo plebeius*, the speech of the lower orders in Rome, which began to creep into literary Latin during the Silver Age. It was a feature of this speech that the suffix "-urio" had lost its desiderative significance. I can put my finger on an instance in the Satyricon of Petronius, a store-house of plebeian Latin. "Et solebas suavius esse, belle deverbia dicere, melica canturire.": "And you used to be a nice fellow, who would recite charmingly and sing little songs." (Petr. 64.) Here "canturire" is put in the mouth of the newly rich Trimalchio as equivalent in meaning to "cantare." From this sermo plebeius the word "micturire," which is of similar form, made its way into the Satires of Juvenal, last of the classical writers, again as a deliberate vulgarity; and it is in meaning equivalent to "mingere," I make water.

> Noctibus hic ponunt lecticas, micturiunt hic
> effigiemque deæ longis siphonibus implent.
> [VI, 309, 310.]

Gifford renders it cleverly thus:

> Here stop their litters, here they all alight
> And squat together in the Goddess' sight.

"Micturition," then, is a word formed on the verb "micturio," I pass water, with suffix "-ition" denoting action. The meaning is the action of passing water, and current medical usage, including such a phrase as frequency of micturition, is justified. But why did we go to the sermo plebeius for the word? I conjecture that he who coined it was one who knew his Juvenal and liked "micturition" better than "minction," but was not quite alive to the rather gross character of the word he chose.

Orpington. H. ST. H. VERTUE.

BRAIN AND MIND

SIR,—In your leading article of Sept. 6, you say: "When we look for the site of storage of 'memory traces' we are making the assumption that these are states of neurones and therefore to be found somewhere in the brain. They might, however, be psychical, and therefore not in the brain at all."

The traces left after neurone activity are a breakdown of glucophosphate complexes (with a change of adsorbed potassium to the ionic form); a lowering of the tissue pH; and a local redistribution of organic substances (such as acetylcholine, originally confined to the neurone itself) and of inorganic ions. The acidity and ionic changes cause local swelling of the tissue with displacement of the gyri (for which the arachnoid-dura structures are particularly well adapted). This stretches neighbouring vascular networks, causing constriction of some with local ischæmia (thus conserving the lost potassium, &c., for use in repair). Subsidence of the swelling occurs with access of adrenaline, and a reactive hyperæmia sets in to remove metabolites, restore ionic equilibrium, provide oxygen and glucose for restoration of the neurone injury, and increase the pH of the tissue —thus restoring a threshold of stimulation a to renewed activity.

An important permanent effect of this repair universally neglected—namely, the local growth capillaries during the hyperæmic process. This has and cannot be seen directly as a result of activity the brain, but it may be safely inferred from that to occur in other parts of the body in similar processes. The Clarks [1] showed that the capillaries the rabbit's ear grew beneath an observation wind as much as 0·4 μ per min., and something of this or even much less is sufficient to account for a permeable reflex pathway in the central nervous s on all subsequent occasions. In a previous publicati I have shown how the pattern of capillary flow synapses mechanises, and gives an intelligible representation of the mental counterpart o activity. Memory traces are thus to be inter a growth of capillaries amongst the neurones. neurobiotaxis can occur must be conceded from work, but apart from this there is no need to as you do, that memory traces are either st neurones, or incorporeal and not in the brain.

Birmingham. F. A. PICKWORTH

ABUSE OF THE EMERGENCY BED SERVICE

SIR,—I would like to reply to Dr. Kagan's letter Oct. 4, because, my handwriting being admitte illegible, I am probably one of the doctors concerned.

In the early hours of the morning I was called to a young man who told me that he had been seized violent abdominal pain in the middle of the night. was unaccompanied by diarrhœa and he had vomit twice. His temperature was 99·2°F and pulse-rate per min. There was tenderness over McBurney's po and slight guarding. Rectal examination (there was c made) evinced tenderness. There was no doubt in mind that the patient had appendicular colic and shou be removed to a hospital for observation and, if necessa surgery.

I explained the situation to the Emergency B Service, telling them I thought the patient need observation in hospital as he was living a long way fr me and there was no opportunity for me to see h again that day. They kindly arranged for him to sent to the Westminster Hospital. When seen th several hours later there were apparently no physi signs and the patient was duly sent home.

I hope that the E.B.S. will continue to help us in difficulties as they have so valiantly done hitherto, a not be influenced by the finger-wagging of our omn cient juniors. If *occasionally* a case is sent which do not merit immediate attention, it is better thus th that cases should be neglected for fear of criticism fr the resident staff.

London, W.1. E. M. HERBERT.

SIR,—I should like to give a further example of t abuse of the Emergency Bed Service, because in agre ment with Dr. Kagan I feel it is a great pity that unfair advantage should be taken of this excelle service.

The E.B.S. rang up a certain London hospital aski if it could admit a child with bronchopneumonia. T medical officer asked the E.B.S. to ascertain for su whether or not there was an associated gastro-enterit because the ward was full of very young infants a there was no isolation available for a new admissio The E.B.S. rang back to the doctor sending in the chi —a medical officer at another London hospital—a was assured that there was no gastro-enteritis and t doctor "would take full responsibility for the case The child was therefore sent along for admission a arrived with gastro-enteritis, otitis media, and a bronch pneumonia. The doctor's letter which came with t case said: "This child has suffered from diarrhœa f 4 days and vomiting for 3 days, with evidence respiratory infection and cough for 2 days. . . . The dia rhœa has been less for the last 24 hours but the stoo are green and slimy."

DEODORISING REFRIGERATORS

r.—Dr. Raghavachari (Sept. 27) claims that 3–4 oz. activated vegetable charcoal—or twice as much nulated charcoal—nicely spread out and allowed to ain in an enamel saucer on the top shelf removed all r from a domestic refrigerator which held a mixture ruit, milk, and other dairy products. In my experi- ts charcoal was tried in large quantities but failed; possible that the circulation of air is better in a stic refrigerator than in the rooms of a large plant. he "refrigeration" odour seems to me to be due to ge number of different substances and *factors*—eanliness, partial decomposition, fermentation, bac- l and fungal proliferation, "natural" odours, slight ages of the refrigerant, cleansing agents, and paint, ention only a few. In commercial refrigerators fruit, t, vegetables, milk, &c., are not kept in one and the e compartment. Perhaps the most lingering, pene- ng, nauseating, and inescapable of the "refrigera- " flavours is that due to ethylene, for which the amine spray is a complete antidote.

Margaret's Hospital, Epping. **FRANK MARSH.**

INTERNATIONAL SURGICAL CONGRESS

ès Honoré Confrère,—Pendant le récent Congrès de ociété Internationale de Chirurgie qui s'est tenu à dres du 14 au 20 septembre, les chirurgiens britan- es se sont multipliés pour permettre aux quelques congressistes venus des pays les plus lointains de se e compte des progrès réalisés dans les installations talières et dans la technique chirurgicale de votre .

ous vous prions d'être notre interprête auprès des rgiens britanniques pour leur exprimer les plus remerciements de la Société et de tous nos confrères ngers pour l'accueil si aimable qu'ils nous ont réservé.

LEOPOLD MAYER
Président.
L. DEJARDIN
xelles. Secrétaire-Général.

HORMONE TREATMENT BY IMPLANTING PELLETS

e,—May I amplify, or qualify, a few aspects of your able annotation of Sept. 27?

lthough I personally follow the surgical technique sepsis, described in your annotation, there are some kers in this country, and at least one large clinic t I visited in America, where the procedure is carried in outpatients and not in a surgical theatre. In t clinic a sharp-pointed trocar and cannula was d, and the site chosen was the anterolateral aspect the upper thigh. Strong 'Elastoplast' binding rounded the limb afterwards to avoid hæmatomas ich were not infrequent, and which in my experience not occur with the blunt trocar that I and others use. have found the subcutaneous abdominal fat a very sfactory site for implantation. The rectus sheath tainly has no advantage, nor has the rectus muscle; d in those cases I have seen in which this deep site s been employed extrusion is at least as frequent. From ries of several hundred implantations I would say that rogens hardly ever extrude: desoxycortone, testo- rone, and testosterone propionate rarely extrude; d progesterone frequently extrudes. In order to avoid s I am attempting to get made progesterone pellets h a thin coating of testosterone or œstrone so that e track of the cannula and the skin incision will be mpletely healed before the progesterone comes in tact with the tissues. There is certainly considerable d for progesterone therapy by this route if it can be ade effective without complications.

To the comparatively innocuous danger of virilism rough too heavy dosage of testosterone, to which r annotation refers, I would add and emphasise the thal danger of too great a dose of implanted desoxy- rtone. It is now generally recognised that desoxy- rtone should not be implanted until several weeks after the patient is stabilised by injections; and even then the initial implantation should be on the low side. As your annotation points out, it is far easier to insert pellets than to remove them.

As regards flooding from an excessive dose of œstrone, there seems to be considerable individual variation, and unfortunately some patients bleed profusely after an implantation of only 30 mg. œstrone. Your warning, therefore, is well justified.

London, W.1. **S. L. SIMPSON.**

MASTOIDITIS AND GASTRO-ENTERITIS

SIR,—Several letters have recently appeared in your journal (Aug. 23, Sept. 13, 20, and 27) concerning mastoiditis and gastro-enteritis in infants. It is conceivable that vomitus might infect the middle ear via the eustachian tube and thence the mastoid cells, but vomiting is not necessarily a feature of enteritis in which middle-ear inflammation is present. We must not forget that this particular parenteral infection is not always a *complication but is often the cause of gastro-enteritis.*

The administration of intravenous fluid with the appropriate salts is so often a life-saving measure that any doubt cast on its safety is harmful and retrogressive. In expert hands exposure during the short operation of introducing the needle is minimal, and with modern technique there is no likelihood of the needle slipping out of the vein. Infants can and should therefore be fed afterwards on a nurse's lap in the correct position.

The incidence of mastoid complications in gastro-enteritis does not seem to have varied much during the last twenty-five years. At the Hospital for Sick Children, Great Ormond Street, it was frequently sought and found in fatal cases long before the days of intravenous-drip therapy.

Climate seems to play a definite part in the frequency of middle-ear infections in infants; and it is interesting to find that this ætiological factor of gastro-enteritis is common at certain seasons in the British Isles, France, and Belgium but rare in Switzerland and Sweden.

London. **BERNARD SCHLESINGER.**

Obituary

EDWARD FFOLLIOTT CREED

M.A., D.M. OXFD, F.R.C.P.

Edward ffolliott Creed, who was the second son of the late Rev. C. J. Creed, died on Sept. 27 at the age of 54. In 1910 he entered Trinity College, Oxford, as a scholar, and took honours in the final school of natural science (chemistry) in 1914. Passing on to King's College Hospital medical school as a Burney Yeo scholar, he took the B.M. degree in 1916, and served in the R.A.M.C., as a captain, working on malaria at Sierre Leone. His early experience and training in scientific laboratory work led him into the pathological department at King's on his return from war service, and he was appointed bacteriologist. On the retirement of Dr. d'Este Emery in 1921 Creed became director of the pathological department, and director of pathological studies in the medical school. Always keenly interested in the clinical side of pathology, he became M.R.C.P. in 1923, later being elected F.R.C.P. in 1932. He took the degree of D.M. in 1927.

"Creed's disposition," writes T. E., "was rather quiet and retiring, but in matters which concerned him, his work or department, he could always state a case with logic and vigour. His shrewd common sense, precise outlook, and retentive memory made him a capital chairman of committees, so that in hospital affairs his advice was always welcome, and it was safe to rely on his sound judgment and balanced consideration. As a teacher the qualities of lucidity and careful preparation were notable in his lectures. Although a hard worker for long hours, he always had time to explain the technical side of any problem, and to give useful suggestions as to some line of investigation; so that to the clinician a chat about the pathological aspects of some puzzling case was always stimulating and instructive. His knowledge was wide and his memory excellent, and one rarely turned to him in vain for accurate and helpful information. For young workers in his laboratory it was a privilege to enjoy the time he would always gladly spend on demonstrating a section or explaining a technique. Nothing was too much trouble to Creed in these matters; and I remember well the pains he took in revealing to us the then complex mysteries of the Wassermann reaction twenty-five years ago. As an examiner his sane judgment made his conclusions fair to the candidates and helpful to his colleagues.

"Creed was not a voluminous writer; but his small output was of high quality; nothing but the best would satisfy his fastidious standards or reach his level of meticulous accuracy. Here was an excellent example both to the clinician who sought his advice and to the young pathologist learning his trade. Although mainly interested in bacteriology, he was also attracted to hæmatology, and carried out some ingenious researches on acholuric jaundice. His early training in chemistry gave him a good appreciation of biochemistry; a long experience of autopsies for coroners completed his equipment in morbid anatomy, so that one may look on him as an all-round pathologist in a sense that is likely to become rare in the future as specialisation divides the subject still more deeply. His colleagues, who were all his friends, will find him hard to replace; those informal chats in his room, on a hundred and one subjects, always stimulating and instructive, and seasoned by his lively humour, will be sadly missed."

Dr. Creed married in 1923 Miss Stella Parker, and he leaves her with two daughters.

CHARLES MARSH BEADNELL

C.B., M.R.C.S., SURGEON REAR-ADMIRAL RETD.

Surgeon Rear-Admiral C. M. Beadnell, who died at Petersfield on Sept. 27, was born in 1872 in a military camp at Rawalpindi, and in a letter written shortly before his death he referred to his birthplace with affection, saying that its proximity to the Himalayas may have accounted for his love of mountains and of climbing them. The eldest son of Major C. E. Beadnell, R.A., a justice of the peace of Montgomeryshire, he was educated at Cheltenham College and at Guy's Hospital where he qualified in 1895. The following year he entered the Royal Navy.

During the American-Filipino war he volunteered as a surgeon, and he was landed with American troops in the island of Luzon, where he saw much fighting. Here he made his collection of human crania illustrating the mechanical effects of modern bullets, which was later exhibited at Haslar Hospital and at the Royal College of Surgeons. For his services with the Naval Brigade in the Boer war he was mentioned three times in despatches, and was awarded eight years' special accelerated promotion to staff-surgeon.

When the King and Queen of Spain travelled to England on H.M.S. *Renown* in 1907 Charles Beadnell was the medical officer of the ship, and he also served in the flagship on the China Station, H.M.S. *King Alfred*. During the 1914–18 war he served on the *Shannon* in the North Sea and later on the *Vernon*, torpedo school. He was promoted surgeon captain in 1919 and surgeon rear-admiral three years later. In 1922 he served as British representative of Army and Navy medical services at the International Congress of Surgeons at Washington, U.S.A. In 1923 he was appointed to the command of the R.N. Hospital at Chatham, and he held this post and acted as naval member of the Medical Consultative Board of the Admiralty till he retired in 1926. He was appointed C.B. in 1924.

On his retirement Admiral Beadnell became a director of the Rationalist Press Association, and soon after its president. His wide and varied interests are clearly shown by the list of his publications, which ranged from such naval topics as *Small-bore Projectiles*, *Disposal of Wounded in Naval Warfare*, and *Environmental Factors Afloat* to the *Evolution of Speech*, *Picture-book of Evolution*, and *Origin of the Kiss*. He also compiled a workmanlike *Dictionary of Scientific Terms* and an *Encyclopædic Dictionary of Science and War*.

Beadnell's special interest in evolution made him a rationalist early in life; indeed he confesses that before he left Guy's Hospital he was "a devout Agnostic." His views, of course, were not always acceptable to his superior officers, although his sincerity and tolerance usually made it possible for him to speak. Describing one of the lantern lectures he used to to the lower deck, he writes:

> At the eleventh hour—all my slides had been arrang
> a messenger came to say "the Commander-in-Chief wis
> attend, Sir." What could I do? I went on the stage
> my heart in my mouth thinking "My goose is properly co
> this time." The lecture went off well. The slides were exc
> man's tail, his gill-clefts, the relationship of his old s
> bladder to his present-day lungs were all shown. The "
> man" made a very nice and appreciative speech. I "tu
> in" well pleased with the course of events. Next mor
> however, the sentry came to the sick bay to say the Ad
> wanted to see me. I repaired to the "cuddy" with a
> feeling. He was very pleasant, however, and after a while
> "I enjoyed your lecture very much, but on second tho
> Fleet-Surgeon, Adam and Eve are good enough for me!"

Admiral Beadnell married Ellen Louisa, daught
George Bailey, of Gloucester, who survives him.

Births, Marriages, and Deaths

BIRTHS

CROFTON.—On Oct. 2, the wife of Dr. John Crofton—a son.
GRAY.—On Sept. 26, at Edinburgh, the wife of Dr. W. D. Gr —a daughter.
HAMBLY.—On Sept. 30, to Dr. Elizabeth Hambly (née Cadbur wife of Mr. Edmund Hambly, F.R.C.S.—a son.
REWELL.—On Oct. 4, in London, the wife of Dr. R. E. Rewell—a daughter.
ROSS.—On Oct. 2, at Edinburgh, the wife of Dr. R. W. Ross—a so
SWAN.—On Sept. 28, to Dr. Elizabeth B. Swan (née White), the wife of Dr. W. D. Swan, of Coxtown, co. Donegal—a son.
WALKER-TAYLOR.—On Oct. 4, in London, the wife of Dr. P. M Walker-Taylor—a son.
ZUCKERMAN.—On Sept. 26, at Birmingham, the wife of Prof. Solly Zuckerman, M.D., F.R.S.—a daughter.

MARRIAGES

HOUGHTON—SWIFT.—On Sept. 27, at Leighton, Salop, Paul Wi chester Houghton, F.R.C.S., to Jean Hallam Swift.
YOUNGMAN—CHRISTOPHERSON.—On Oct. 1, at Reigate, Richard Youngman, M.B., to Nancye Clifford Christopherson.

DEATHS

BEADNELL.—On Sept. 27, at Steep, Hants, Charles Marsh Beadn C.B., M.R.C.S., surgeon rear-admiral, R.N. (retd.).
BURNS.—On Sept. 27, at Bournemouth, William George Burn M.A., M.B. Aberd., aged 52.
CREED.—On Sept. 27, Edward ffolliott Creed, M.A., D.M. Oxf F.R.C.P., D.P.H., aged 54.
EVANS.—On Sept. 20, at Chichester, Nelly Evans, L.R.C.P. aged 77.
GAGE.—On Oct. 4, in London, Harold Courtney Gage, M.R.C.S. F.F.R.
HARKER.—On Oct. 4, at Southport, Thomas Henry Harker, M.B. Lond.
JONES.—On Sept. 28, Ronald Trevelyan Jones, M.R.C.S.
ROBERTS.—On Sept. 27, Wilfred Hugh Roberts, V.D., M.R.C.S.
STOCKER.—On Sept. 28, at Bournemouth, Walter Woodley Stocke M.R.C.S., aged 82.

Notes and News

ROYAL COLLEGE OF OBSTETRICIANS' DINNER

At a dinner given by the Royal College of Obstetricians and Gynæcologists in London on Oct. 3, Mr. Aneurin Bevan, Minister of Health, commended the college for establishing close association with the Empire. He hoped that he would be spared to carry to maturity the great schemes on which the Ministry of Health was launched. There was, he said, a gratifying rise in the birth-rate and fall in the infantile and maternal mortality-rates; this was due not only to specialist skill but to the collective intelligence of the population. In reply Mr. William Gilliatt, the president, recalled that whereas the Royal College of Physicians was granted its first Royal Charter in 1518, and the Royal College of Surgeons in 1800, the Royal College of Obstetricians received its first royal charter as recently as last March; but, despite its youth, the college already had a record of useful achievement. It was a truly British college, with reference committees in the Dominions; the committee in Australia had been raised to the status of regional council and granted a fair degree of autonomy. Sir Herbert Eason and Mr. F. A. Maguire, chairman of the regional council in Australia, replied to The Guests, proposed by Mr. H. R. MacLennan, who suggested that obstetricians came of humble stock: "We are," he said, "the lineal descendants of Sarah Gamp."

CENTENARY OF THE AMERICAN MEDICAL ASSOCIATION

The American Medical Association was founded in 1847, mainly through the efforts of Dr. Nathan Smith Davis, then in his thirtieth year and in general practice in Broome county, New York State. He lived to attend the association's jubilee meeting in 1897, when, "in a voice that all could hear," he gave an address on the origin and development of the association, and he died in his eighty-eighth year, having practised his profession for 67 years. The hundredth anniversary of the association's founding was celebrated at the centennial session in Atlantic City, in June, and a book[1] has been published in recognition of that occasion. It includes a history of the association written by Dr. Morris Fishbein, editor of the *Journal of the American Medical Association*, biographies by Dr. W. L. Bierring, and portraits of the 101 distinguished medical men who have been president; and it also describes the various "councils and bureaus" through which the association's activities are discharged. The result is a volume that cannot fail to interest doctors of whatever nationality. Specially noteworthy are the particulars given of the exposures made through the *Journal*, of "charlatans, low-grade medical schools, and fraudulent proprietary medicines." Readers who know little of this subject may find it hard to decide which is the more astonishing and deplorable, the brazen effrontery and success of the quacks or the abysmal folly of their dupes. British readers will note with interest that Dr. George Henry Simmons, whose work for the association was second in importance to that of the founder only, was born in England and emigrated to the United States at the age of eighteen. From 1899 to his retirement in 1924, as secretary and general manager as well as editor of the *Journal*, he made the association an influence of national importance.

A PERSPECTIVE OF DOCTORS

The 20th Century-Fox series of "March of Time" films has lately been augmented by a new short documentary, *Your Doctor Today*. Alastair Cooke, who gives the commentary, refers to the advances of recent years, such as the sulphonamides, penicillin, and streptomycin. The film shows the New York Academy of Medicine, now celebrating its centenary, and reviews some work in the great American hospitals, including the use of the artificial kidney, transfusion of a baby suffering from hæmolytic disease of the newborn, and the treatment of cancer with radioactive isotopes. All this is good, but the sequence on British medicine is curiously unrepresentative, showing only the treatment of industrial neuroses at Roffey Park, and a corner of a laboratory at Oxford where Dr. V. G. Korenchevsky is investigating longevity. It seems likely that 20th Century-Fox had difficulty in persuading most British centres of research to contribute to the film; and the result is a review which covers the two items mentioned with restraint and good sense, but gives no idea whatever of British medicine as a whole. Those who refuse to collaborate in this reasonable and informative kind of journalism might pause to consider the effect of such omissions on American—and indeed on British—opinion of our medical work.

CLASSROOM ATMOSPHERE

Before the war between three-quarters and one million tons of fuel were used each year for the heating of our schools, at a cost of about 5s. per child. A committee appointed by the building research board of the Department of Scientific and Industrial Research recommends in its report[2] a classroom temperature of 57–60°F. Of the heat lost from the classroom, 30–50% goes by ventilation, 20–30% through the roof, and 20–25% through the windows; thermal insulation and the installation of heating plant no larger than is essential may, it is suggested, help to achieve considerable economy. Moreover, double-glazing will halve the heat lost through a closed window. Pipes or tubular heaters at skirting level along three sides of the room probably give the most equable warmth; but these are difficult to clean and have been superseded by radiator systems. Floor-heating, the committee suggests, should be more widely employed; it has the great advantage of keeping the feet warm, and it takes up no floor-space.

For ventilation the report lays down as a minimum winter standard 1000–1500 c. ft. of fresh air per hour per pupil. This can be achieved in most classrooms by 5–7 air-changes per hour; and it should still be possible to keep the air velocity in the body of the room within the range of 20–40 ft. per min. In providing cross-ventilation hopper-windows should be fitted with side cheeks to prevent the incoming air being blown directly on to the children nearby; and a heating surface should be placed below the windows to counteract the cool down-draught. The committee finds no virtue in continuous windows along one side of the room, opening down to floor level—a practice which prevents the installation of a heating system along this wall.

ON USING AN ARTIFICIAL LIMB

The Ministry of Pensions have published an informative little booklet[2] of hints to users of artificial limbs. It encourages a confident attitude towards the limb, advises about special movements—for example, which foot to use when mounting stairs or descending from buses—suggests clothes for the limb and the way to put them on, reminds the wearer to look after his stump properly, and supplies some notes on the care of the limb itself. A paragraph on sport and recreations shows how little of a handicap an artificial limb can be. It is a useful booklet, which does not pretend to be comprehensive. Those who have further hints to add are asked to send them to the Director of Medical Services at the Ministry.

THE CHALK PIT MURDER

Last November the dead body of a decent harmless man named Mudie, employed as barman in a Surrey hotel, was found in a chalk pit near Woldingham. He had been gagged and trussed up and apparently subjected to some violence before his death from asphyxia, due to the tightening of a rope round his neck. The murder was planned by Thomas Ley, a rich Australian obsessed with insanely jealous suspicions of an elderly woman who had ceased to be his mistress many years earlier. He had suborned Smith and others (three of whom turned "King's evidence") to dispose of Mudie. The facts were clear. The two accused, Ley and Smith, were found guilty.[3] A fortnight after the Court of Criminal Appeal had refused to interfere, Ley was reported insane and removed to Broadmoor where he died of a seizure some two months later. The capital sentence on Smith was commuted when Ley was found insane.

[3] Trial of Ley and Smith (Notable British Trials Series, vol. 69). Editor: F. TENNYSON JESSE. London: Wm. Hodge. 1947. Pp. 313. 15s.

The sole medical interest of the case lies in the fact that Ley's obvious madness, discovered as soon as the law had secured the verdict of "guilty," could never be mentioned at the trial or on appeal. He chose to make a persistent denial of the charges; his learned counsel therefore could hardly pursue, as an alternative and much more hopeful defence, a plea of "guilty but insane." His earlier career had apparently included queer events which might have led to criminal proceedings; yet he had discharged without discredit the high office of Minister of Justice in Australia. So much we now learn from the introduction which Tennyson Jesse contributes to the story of the crime.

Royal College of Physicians of London

Dr. Janet Vaughan will deliver the Bradshaw lecture on Thursday, Nov. 6. She will speak on the Anæmia associated with Trauma and Sepsis. On Tuesday, Nov. 11, Mr. Harold Nicolson will give the Lloyd Roberts lecture on the Health of Authors. Both lectures will be held at 5 P.M. at the college, Pall Mall East, S.W.1.

Royal College of Obstetricians and Gynæcologists

On Oct. 3, to mark the grant of the Royal Charter to the college, the honorary fellowship was conferred on Sir Ewen Maclean, Sir William Fletcher Shaw, Prof. C. G. Lowry, and Prof. J. M. Munro Kerr, who are the four remaining signatories of the articles of association whereby the College was incorporated.

Postgraduate Course on Rheumatism

A weekend course on the chronic rheumatic diseases, for general practitioners and demobilised officers, will be opened by Lord Moran at St. Stephen's Hospital, L.C.C., Fulham Road, S.W.10, on Saturday, Oct. 25. Full details can be had from the Fellowship of Post-Graduate Medicine, 1, Wimpole Street, W.1.

Universities Federation for Animal Welfare

On Friday, Oct. 17, at 5.15 P.M., in the anatomy theatre of University College, Gower Street, London, W.C.1, Dr. H. R. Lillie, surgeon to an Antarctic whaling fleet, will open a discussion on Whaling Today—the Search for a Humane Method of Killing. Admission to the meeting is free.

R.A.F. Temporary Commissions for National Service Entrants

Doctors and dentists doing their national service in the Air Force will be in future granted temporary instead of emergency commissions. National-service men holding temporary commissions in the Medical and Dental branches may apply for short-service commissions.

Centenary of the Discovery of Chloroform Anæsthesia

On Tuesday, Nov. 4, the University of Edinburgh is celebrating the discovery of chloroform anæsthesia by Sir James Simpson in 1847. At 9.30 A.M. a scientific meeting to discuss the Use of Chloroform at the Present Date will be held in the surgery department, University New Buildings, when papers will be read by Prof. R. R. Macintosh, Dr. D. S. Middleton, and Dr. John Gillies. At noon there will be a laureation ceremony when the honorary degree of doctor of laws will be conferred on Dr. H. W. Featherstone and Mr. T. B. Simpson, K.C. At 3.45 P.M. Dr. Douglas Guthrie will give an address with a display of relics. The display will be open in the upper library of the Old College from Nov. 3 to 7 from 10 A.M. to 4.30 P.M. daily.

Regional Boards' Appointments

Scottish Western Region: Sir Alexander Macgregor has been appointed chairman of this board in place of Prof. E. P. Cathcart, who has asked to be relieved of the appointment on account of ill health. Sir Alexander Macgregor was medical officer of health for Glasgow from 1925 until his retirement in 1946.

The following appointments as senior administrative officers of hospital boards have been made: *South-western region:* Dr. G. C. Kelly (a senior medical officer of the Ministry of Health); *East Anglian region:* Dr. J. B. Ewen (principal assistant medical officer, hospitals section, Middlesex County Council). Mr. K. V. F. Morton has been appointed secretary to the East Anglian region.

Central Midwives Board for Scotland

As a result of a reallocation of duties, Mr. N. D. Wa the Department of Health for Scotland has been appoi a member of the board in place of Mr. T. A. Greig.

Irish Tuberculosis Society

At a meeting of this society to be held at Crook Sanatorium, co. Dublin, on Friday, Oct. 17, at 5 P.M., D Arthur Walsh will speak on Trends in Treatment of Pulmo Tuberculosis in Scandinavia; Dr. Pearl Dunleavy on Dispen Organisation in Tuberculosis in Scandinavia; and Dr. P Edwards on Some Essential Requirements in Tubercul Schemes.

CORRIGENDUM.—The specific antigenic reaction for coidosis described by Prof. Haxthausen at the Internati Conference of Physicians (*Lancet*, Sept. 20, p. 445) wa Kveim reaction.

Diary of the Week

OCT. 12 TO 18

Monday, 13th

ROYAL COLLEGE OF SURGEONS, Lincoln's Inn Fields, W.C.2
5 P.M. Prof. Ian Aird: Surgery of the Biliary System.
6.15 P.M. Dr. W. W. Mushin: Signs of Anæsthesia.

SOCIETY OF APOTHECARIES OF LONDON, Black Friars Lane, E.C
5 P.M. Dr. T. F. Cotton: Heart-failure and its Treatment.

MEDICAL SOCIETY OF LONDON, 11, Chandos Street, W.1
8.30 P.M. Pathological meeting.

WESTMINSTER HOSPITAL, Horseferry Road, S.W.1
5 P.M. (Meyerstein lecture theatre.) Clinico-pathological Dem stration on Anterior Poliomyelitis.

Tuesday, 14th

ROYAL COLLEGE OF SURGEONS
5 P.M. Mr. C. E. Shattock: Appendicitis.
6.15 P.M. Dr. Mushin: Spinal Analgesia.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole Street, W.1
5 P.M. *Psychiatry.* Sir David Henderson: Psychiatric Hy thesis and Practice. (Presidential address.)

LONDON SCHOOL OF DERMATOLOGY, 5, Lisle Street, W.C.2
5 P.M. Dr. I. Muende: Pathological demonstrations.

EDINBURGH POST-GRADUATE BOARD FOR MEDICINE
5 P.M. (Royal Infirmary.) Dr. R. McWhirter: Living Cryst

Wednesday, 15th

ROYAL COLLEGE OF SURGEONS
5 P.M. Mr. Grant Massie: Neoplasms of the Colon.
6.15 P.M. Dr. E. A. Pask: Resuscitation.

ROYAL SOCIETY OF MEDICINE
5 P.M. *Comparative Medicine.* Mr. R. E. Glover, F.R.C.V. Influence of the Small Animal Breeder on Biolo Research. (Presidential address.)

SOCIETY OF APOTHECARIES OF LONDON
5 P.M. Dr. R. D. Lawrence: Diabetes—New Theory and Tre ment.

UNIVERSITY OF GLASGOW
8 P.M. (Department of Ophthalmology.) Prof. A. J. Ballanty Ophthalmoscopic Diagnosis.

Thursday, 16th

ROYAL COLLEGE OF SURGEONS
3.45 P.M. Prof. John H. Garlock (New York): Surgical Treatme of Carcinoma of the Œsophagus and Upper Stomach.
5 P.M. Sir Stanford Cade: Cancer of the Mouth.
6.15 P.M. Dr. R. M. Johnson: Intravenous Anæsthesia.

ROYAL SOCIETY OF TROPICAL MEDICINE & HYGIENE, 26, Portland Place, W.1
7.30 P.M. Sir Philip Manson-Bahr: Practice of Tropical Medicine in London. (Presidential address.)

SOCIETY OF APOTHECARIES OF LONDON
5 P.M. Mr. Kenneth Walker: Modern Views on the Treatme of Venereal Disease.

HONYMAN GILLESPIE LECTURE
4.30 P.M. (Edinburgh Royal Infirmary.) Dr. A. S. Paters Electro-Shock and Electronarcosis in the Treatment Mental Disorders.

Friday, 17th

ROYAL COLLEGE OF SURGEONS
5 P.M. Mr. Murray Falconer: Principles and Results of Lumbar Intervertebral Disk Surgery. (Hunterian lecture.)
6.15 P.M. Dr. Massey Dawkins: Epidural Analgesia.

ROYAL SOCIETY OF MEDICINE
8 P.M. *Obstetrics.* Dr. Helen Payling Wright, Dr. Ma Haines, Mr. A. Dickson Wright, and Mr. Leslie William Postoperative Thrombosis.
8 P.M. *Radiology.* Dr. R. G. Reid: Interatrial Septal Defect.

SOCIETY OF APOTHECARIES OF LONDON
5 P.M. Dr. H. Stanley Banks: Meningococcal Disease.

LONDON CHEST HOSPITAL, Victoria Park, E.2
5 P.M. Mr. T. Holmes Sellors: Surgery of the Heart and Per cardium.

ROYAL MEDICAL SOCIETY, 7, Melbourne Place, Edinburgh
8 P.M. Marquess of Linlithgow: Medical Rehabilitati (Inaugural address.)

CYSTIC DISEASE OF THE BREAST

HUMAN AND EXPERIMENTAL*

B. D. PULLINGER
M.D. Lond.
CE MEMORIAL FELLOW, IMPERIAL CANCER RESEARCH FUND

HE three outstanding questions concerning cystic ease of the breast are the site and mode of origin of cysts, their cause, and their relation to cancer of the ast. Is such relation fortuitous or causal? According Cheatle and Cutler (1931) 20% of all mammary cancer gins in cystic breasts.

hese three questions have been investigated most gently for over 100 years since Brodie's lectures and ical account (1846). The work falls into descriptive, culative, and experimental phases. We are now in experimental period, and it is my object to examine cally what has been achieved in this direction and t still needs to be done.

Before these lesions were seen or reproduced experi-ntally in animals, there was a phase of speculation out the cause of the cysts. That stage of it, due to a hion in the latter part of the last century which ated everything to bacterial inflammation, may now, the light of greater knowledge, be ignored. Its merits re that attention was focused on the chronic nature d frequent localisation of the disease.

The first suggestion of a more probable cause was d on the known physiological relationship between ovaries and the mammary glands. From about 1895 erimental evidence began to accumulate opposing the w that nerves were primarily concerned in stimulating growth of the mammary gland, which up to then vailed. It was found that removal of the ovaries rested normal changes in the reproductive system, cluding development of the mammary glands, whereas bsequent transplantation of ovarian tissue led to ewed activity and growth. The hormone theory then king shape was early applied to treatment of breast ease. Lett (1905) suggested that a morbid variation the secretion of the ovary might be one of the pre-sposing causes of cancer of the breast. Speculating rther on the relation between ovarian secretion and ronic cystic disease Lett wrote:

> "Carcinoma, as is well known, not infrequently develops in a breast which is already the seat of a chronic mastitis, and it may be that there is a connexion between the secretion of the ovary, one or more of the varieties of chronic mastitis, and mammary cancer."

CYSTIC DISEASE OF MICE

This association, forecast in 1905, between the secretion the ovary, one variety of cystic disease, and mammary ncer, has since been substantiated in rats (Geschickter 45) and mice (Goormaghtigh and Amerlinck 1930). he question that has now to be asked is: does this sociation in rodents correspond to a similar condition the human female? One must expect variations etween the human and animal diseases based on ariation in normal anatomy and physiology. The uman mammary gland is far richer in connective tissue. here is little in comparison in the normal mouse but ore in the rat. Both anatomical development and hysiological maturation of epithelial elements in the rgan in human and animal species differ consider-bly owing to differences in structure and in the varian cycle. Whereas in the human after puberty here are both œstrogenic and luteal ovarian phases, here is in unmated mice and some rats no luteal hange.

According to most observers the effects of ovarian hormones on mammary glands of all species are twofold: œstrogens, whether natural or synthetic, cause duct outgrowth; and progesterone is responsible for lobular-alveolar differentiation. The debatable subject of the exact mode of action of these hormones, whether partly or wholly direct, or whether the pituitary gland is intermediary, need not now be discussed. The point is that all agree that two hormones, follicular and luteal, are required for full development of the gland by whatever route they operate.

The data imply that in unmated rats and mice (and a few other animals) which are not pregnant or pseudopregnant no lobular-alveolar development with acinus proliferation can be expected. In the young human female, on the other hand, after puberty and in the absence of pregnancy, a certain but variable degree of lobular-alveolar differentiation is normal and due to secretion of some progesterone from the corpus luteum accompanying menstruation. It is necessary to know the relationship of ovarian hormones to the development of glandular elements, and the differences between the human gland and those of rats and mice, if one is to follow the experimental work.

Goormaghtigh and Amerlinck (1930) claimed to have reproduced Reclus' cystic disease of the breast by repeated daily subcutaneous injections of an œstrin-containing extract into ovariectomised female mice. What they had achieved with this extract was as follows: they had induced extensive development of all the mammary glands and caused abundant lobular-alveolar differentiation in 9 out of 11 mice, though this response is supposed to be specific for the luteinising hormone. The luteinising hormone was not present either as an endogenous product or as an artificial application in the experiment. Further, there was cystic dilatation, with milky secretion into the dilated ducts. There were also nodular adenomatous collections of acini, and 1 mouse out of 11 had developed a mammary carcinoma. Here was a reproduction of human cystic disease with one of its problems (the cause) apparently solved and another (the relation to cancer) intruding again.

These changes were not uniform in the glands. They appeared irregularly in different parts, and some mammæ were unaffected. Whereas some of the ducts were distended with secretion, others were solid, filled with hyperplastic epithelial cells. When the changes in this experimental condition are compared with the final product of the descriptive study of the human disease (Cheatle and Cutler 1931), there is a rather close correspondence in spite of the underlying structural and physiological differences between the two species, as shown in the accompanying table. One of the most remarkable features of Goormaghtigh and Amerlinck's (1930) results was the non-specific development of lobules of acini in response to œstrogen alone; another was the appearance of a milky secretion. This, as mentioned before, was to be expected only if luteal and possibly other pregnancy hormones were present. Little attention has been given to this important feature. Whatever the explanation, this development certainly made the likeness between the disease in the mature but non-pregnant human gland and the experimental œstrogen-treated animal glands.

NEED FOR STANDARDISED ANIMALS

Besides this close resemblance between the human and animal condition due in the latter to an atypical response to œstrogen in some of the mice, another point requires special notice. Though Goormaghtigh and Amerlinck's 11 mice were all treated almost exactly alike, 2 did not respond by developing a cystic state after receiving excess of œstrogen.

---

* Imperial Cancer Research Fund lecture delivered in December, 1946.

COMPARISON OF HUMAN AND MOUSE CYSTIC MAMMÆ

—	*Human cystic disease (Cheatle and Cutler 1931)*	*Experimental cystic state (Goormaghtigh and Amerlinck 1930)*
Cause.. ..	Unknown (disordered ovarian secretion suspected since 1905)	Extract of ovary containing œstrogen injected subcutaneously
Total incidence	Unknown	In 9 of 11 mice
Duct changes	Proliferation of smaller branches; dilatation macroscopically visible in smaller and terminal branches above 1–2 mm. in diameter; distributed in both breasts, one whole breast, or one lobule	General proliferation; dilatation visible macroscopically only when ducts are distended with milky secretion; some microscopical distension; distributed variously in 9 of 11 mice, either focal or widespread; no change in 2 of 11 mice
Contents of ducts	Fluid secretion (not inflammatory) thin, clear, or thick greenish, sometimes creamy (turbid, milky, or cheesy *); colostrum cells; desquamated hyperplastic duct epithelium; "pale" cysts common; irregular presence of periductal leucocytes	Fluid secretion often milky and concretous (many authors); colostrum cells (later authors); some ducts solid with epithelial cells; no desquamation, or very rare; no "pale" cysts in mice, some in rats; irregular presence of periductal leucocytes
Acini	Proliferation variable; dilatation	Proliferation regular and widespread (in 9 of 11 mice); dilatation and secretion

* G. Keynes

Here a digression must be made to explain that these observations were made in 1930, when a mouse was still just a mouse, and in laboratories, though not to fanciers, one mouse was thought to be quite the equal of another and just like it. But even then cancer workers knew that in at least one respect individual mice and stocks of mice differed. Some female mice developed cancer, whereas others did not, and some stocks had regularly a high incidence of mammary tumours, whereas others did not.

The breeding of these stocks was preceded by the work of Murray (1911), who in the Imperial Cancer Research Fund's laboratories had shown that female mice in whose ancestry cancer of the mamma had occurred not further back than the grandmother were distinctly more prone to develop cancer than were those in whose ancestry the disease was more remote. Geneticists also knew of heritable differences in mice and how they were inherited. A vigorous and finally successful attempt was begun in the U.S.A. to find out if cancer were truly hereditary and, if so, how it was inherited. Geneticists bred mice derived from various stocks in such a way as to make them identical. This was done by brother-and-sister or parent-and-offspring matings for so many generations that, according to mathematical calculation, the mice were approximately homozygous—i.e., the genes in each chromosome might be supposed to be identical with those on the homologous chromosome in about 98% of mice. So-called pure-line strains of mice are the result of this strict inbreeding for 20 or more generations. So far as concerns cancer, strains were developed in which the breeding females had either no mammary tumours, or a medium incidence, or a high incidence of 80–100%.

HIGH-CANCER AND CANCER-FREE STRAINS

Though the whole subsequent story of the man which mammary cancer in mice is inherited has been told, the discoveries of Little and his coll and of Bittner (American Association for the Adv ment of Science, 1945) must be briefly summ The mammary cancers which are apparently inh in these inbred strains are due not to true chromo inheritance, though this plays a part, but in the analysis to the presence in the mother's milk of a tum causing agent.

If newborn mice are removed from their own c prone mothers at the moment of birth and put to suckled by a mother from a mammary-cancer-free the young cross-suckled females, when they gro and breed, do not develop spontaneous mammary If left to be suckled by their own mothers they do. implies that the agent that causes the tumours is mitted in the mother's milk. It is not transmitt the males. (In exceptional experiments it app pass by other routes.)

Besides the transmission of the tumour agent Americans found two other conditions that were ess if the agent was to become effective in causing a tum in every mouse suckled. They found that the soil be receptive. The mammary gland must be under influence of œstrogen, and the mice must be derived a susceptible strain. In this latter instance the q of susceptibility was found to be inherited by c somal transmission. This was found out by d opposite experiment. Mice from a low-cancer were transferred to be suckled by mothers from a cancer strain. The incidence of cancer in these su when they grew up and bred depended greatly presence of relationship with a high-cancer strain. was as high as that characteristic of the foster m strain only in the first generation of hybrids father was derived from a high-cancer strain. In circumstances the transferred milk-borne agent become active, but the incidence of tumours was

The purpose of this digression has been to show not all mice are alike, but from some points of they can be made so. So far as concerns the pr under discussion, the differences between mice that be fixed or standardised are twofold. First, there strains of mice with a high incidence of mamm tumours, others with medium *or low incidence,* and others that never develop this type of tumour spont ously. The incidence of tumours depends on posse of a milk-borne tumour agent. Secondly, a high rate pathogenic activity or failure of activity of the age in respect of tumour growth depends on, and reveals th existence of, a receptivity or susceptibility or absence it in various strains. The quality of susceptibility inherited according to mendelian laws. There other accepted way of showing its existence than what may be called the tumour test, though an way may become possible (Pullinger 1947).

Since these discoveries were made, it has bee useful and often necessary to use these pure-line st of mice for all sorts of experiments. For example, was first pointed out by Boyland, of the Royal C Hospital, that experiments on tumour therapy could standardised by growing transplants in these strains. seemed also that, if the response to œstrogens was to investigated in the mammary gland, it was now lo to use pure-line mice, because the individuals might expected to react alike. Discrepancies such as that Goormaghtigh and Amerlinck's (1930) experimen when only 9 of 11 *mice responded atypically,* might disappear. Variable factors might next be introduced will instead of having them upset the results. artificial kind of experimentation has no bearing on response of the human gland to hormones, because

ans are mongrels. This very fact makes it impossible
nalyse variations that may be encountered in physio-
cal response without the aid of standardised
ditions.

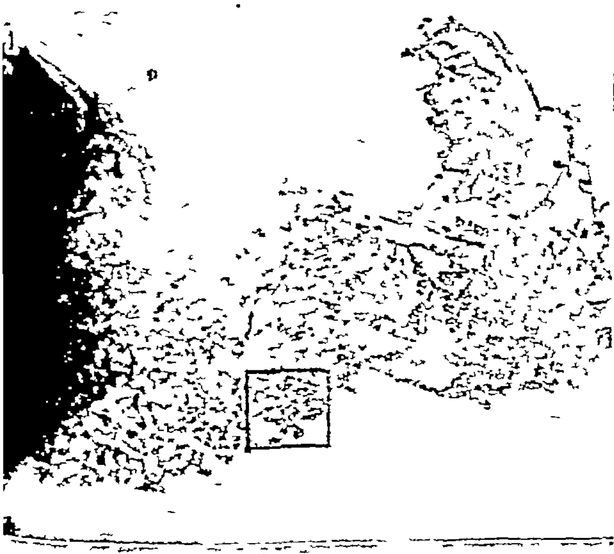
ŒSTROGENS

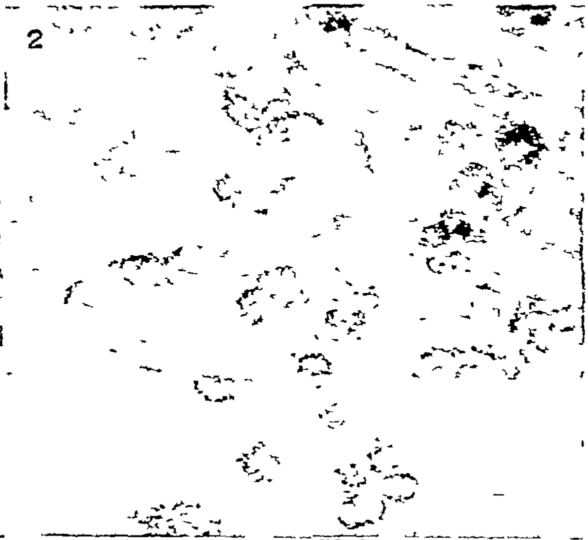
efore starting to test any of the mice for response
estrogens, another step had to be taken and another
ession must be made. Œstrogens are formative
its in the mammary gland. They cause its epithelial
ts to grow and multiply so that, if one wants to find
what œstrogens can do in any strain on either a
ntitative or qualitative basis, all other known
ative agents *must be eliminated from the experi-*
its Other than hormones the only formative agent
wn to be present in some mouse strains is the milk-
ne agent of mammary cancer. If, therefore, the
onse to œstrogen alone is to be examined, the mice
l must be first freed from the tumour agent. It might
rgued that this step is unnecessary, that one could
possibly mistake tumour growth for anything else,
use it is localised and unmistakable. This may be
but it must be remembered that in many of the high-
cer mouse strains mammary tumours are multiple.

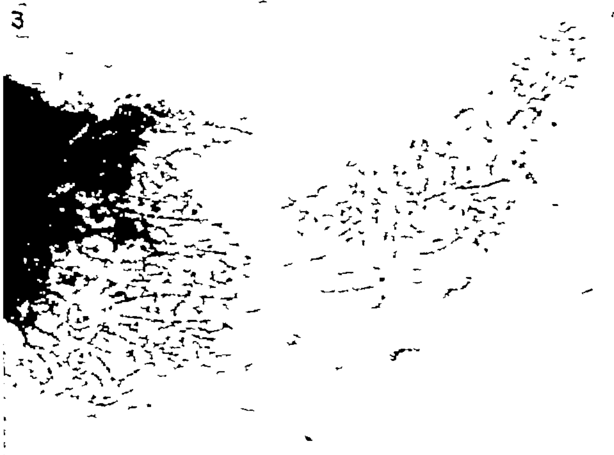
There are also many stages in the process of forming a fully developed malignant tumour. The earlier stages of proliferation are not recognisable as tumours. It could not be said of any particular region that had responded to œstrogen that the milk-borne agent had not taken part. This requirement necessitated the breeding of a special subline of two of the high-cancer strains free from the milk-borne tumour agent. It was done by the method of cross-suckling young from the moment of birth and then breeding from the transferred litters. From the two sublines so obtained from the two strains breeding females were obtained that did not develop tumours in 3–6 years. The mice tested to determine the response of the mammary gland to single or once repeated large doses of œstrogen were young mature virgin females of these strains. To make so far as possible the results comparable by subjecting all the mice to the same dose of œstrogen it was necessary first to remove the largest single source of natural œstrogen, the ovaries.

STRAIN RESPONSES TO ŒSTROGENS

Bilateral ovariectomy was done about the 56th day of life. Œstrogen was applied within 24 hours. If the







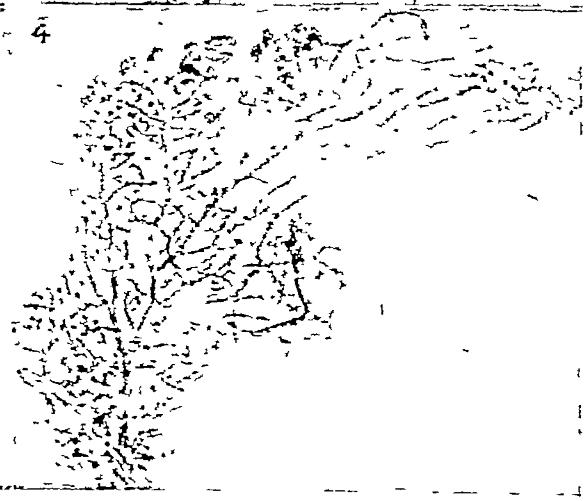


Fig 1—Response to 400 µg. of œstrogen in a 3rd thoracic mammary gland of an R3 mouse deprived of ovaries and of the tumour agent. (× 6.)

Fig 2—Enlargement of field outlined in fig. 1.

Fig 3—Response to 400 µg. of œstrogen in a 3rd thoracic mammary gland of a Strong A mouse deprived of ovaries and of the tumour agent. (× 6.)

Fig. 4—Response to 800 µg. of œstrogen in a 3rd thoracic mammary gland of a first-generation hybrid female deprived of its ovaries, from C57 (black) and R3 parents. (× 6.)

application is delayed longer, the mammary ducts will probably atrophy and subsequently not respond. The œstrogens separately tested were the naturally occurring ones, œstradiol and ketohydroxyœstrin. If these chemicals are dissolved in oil or included in pellets and put under the skin, their rate of absorption is variable and slow. To get a rapid response within a short or limited time, acetone solutions were applied to the skin. The original dose used, 400 μg., was probably excessive. For some purposes it was applied on one occasion only, for others it was repeated after an interval of 20 days. Full details of the experiments and results have been published by Pullinger (1947).

After a single dose of 400 μg. the mammary glands of one of these strains (R3) responded vigorously, similarly and in an unexpected manner to both œstrogens. It was unexpected, when one recollects that the normal response consists of duct outgrowth only. In the test mice of this particular strain, having susceptibility to cancer but no milk-borne agent and no tumours, not only did the ducts grow out and branch extensively but also there was considerable pseudolobular-alveolar development giving rise to clusters of acini and distension of both ducts and acini with secretion. Some of the acini were ballooned out and cyst-like, and the ducts in cross-section appeared cystic. Œstrogen alone produced this change, which, according to previous knowledge of it, should have required the combined action of œstrogen, progesterone, and probably a lactogen. It is a pathological adenosis with secretion and distension (figs. 1 and 2).

This reaction is the cystic disease of mice discovered by Goormaghtigh and Amerlinck (1930) and since confirmed by many others, chiefly in male mice. In the present experiments it has been obtained in a cancer-susceptible strain (R3), after freeing it from the tumour agent, in ovariectomised virgin female mice. It was seen constantly in every mouse examined after treatment with a single large dose of 400 μg. of either œstrogen. This is the condition that has finally to be compared *with human cystic disease of the breast. It is clear, so* far, that it is independent of the milk-borne tumour agent, of cancer, and of failure of involution, and is probably due to excess of œstrogen. The normal output of œstrogen is unknown—only what is excreted and the minimum required to produce œstrus are known—but I have other data which indicate that the dose used was excessive, even from the point of view of causing a pathological rather than a physiological response. The response to 400 μg. was similar for both œstrogens used.

At the time that these atypical responses were obtained by me it was still uncertain that the milk-borne agent had been eliminated, because insufficient time had elapsed for tumours to arise if they were going to do so. It seemed then advisable to repeat the same test in mice of a strain that had never developed mammary tumours in these laboratories nor borne the milk agent. The one next tested (C57 black) gave a typical normal mammary-gland response to both œstrogens similar to fig. 3. By increasing the dose of œstrogen and by prolonging the test period, some slight indications of acinus development could be found but no distension and no milky secretion.

It was clear from this result that there existed a strain difference in response long suspected by others through experiments on male mice. It then seemed possible that the hereditary-susceptibility factor in the causation of tumours might reveal itself morphologically in this capacity to undergo cystic mammary change in response to excess œstrogen.

The next strain (C3H), also having a high incidence of mammary cancer but not freed of the tumour agent, confirmed this suspicion by responding similarly though less uniformly. But mice of the fourth strain (Strong A), also having a high mammary-cancer incidence, responded like normal mice, whether or not the test animals had been freed from the tumour agent (fig. 3). Only *prolonged application of smaller doses* was a seen at length to some localised formation of small Thus it seems certain that the capacity to react by dilatation combined with adenosis-like which is hereditary in certain strains, is not corre with that hereditary factor which underlies susceptib to cancer.

CYSTIC DISEASE IN RELATION TO MOUSE CANC

It is certain also that cystic disease artificially ind in some mouse strains is independent of the can producing milk-borne agent. In this respect the condition conforms to the opinion expressed by and Cutler (1931) that in humans cystic disease disease sui generis and not part of a cancer process. in the mouse is it a prerequisite of milk-borne cancer. It is claimed, however, that in mice of strains that are devoid of milk-borne tumour methylcholanthrene, a powerful carcinogen, can mammary tumours, whether it is applied locally or a distance. Perhaps these methylcholanthrene- tumours are more readily caused in mammæ of strains which respond atypically to œstrogens. T point has still to be decided.

A comparison of cystic disease in rat and mammæ might be even more valuable than in and human, because in rats fibro-adenomas can induced as well as cystic disease and (Geschickter 1945). Rat strains are not yet from long pure-line inbreeding, nor has a separation the tumour-producing stimulus been found and This renders them unsuitable at present.

In this comparison between the mouse cystic sta and human cystic disease some discrepancies still rem These concern the localisation of the disease, the ex process by which it arises, and its hereditary basis in mi

LOCALISATION IN MOUSE AND HUMAN SUBJECTS

In the human, both breasts, one breast, or one lob may be affected. This is curious if the disease is cau by an excess of hormone, which one might expect to distributed evenly by the blood-stream. In the mou when one examines responsive inbred strains, peculiar reaction is found in every part of every gla It is at this stage that one can deliberately introdu complication into the experiments. *Having got* a dard response in pure-line inbred mice, one can gradually from the known to the unknown and in turn hybrids derived from peculiar reactors an normal reactors and then unselected mongrel mice.

Hybrids were bred from two strains, one (R3) reacti vigorously and atypically, the other (C57 black) normall by duct outgrowth only. First-generation female proge only were tested, and that hybrid which lacked th milk-borne agent (C57 × R3) was chosen. A double do of twice 400 μg. of œstrogen was given. The results curious. Part of each mamma reacted like one paren part like the other, the proportion being about half half (fig. 4). Every female of all litters examine responded similarly. The division into two parts *seldom quite exact. If ducts from* the non- half were traced back, it was usually possible to one that, on the whole, reflected the non-reacting paren yet here and there carried on it a few cystic acini. I many specimens there was a suggestion that a positio at the periphery of the gland favoured cystic chang but this was not always so. The dual response in the hybrid mice suggests that localisation of cystic respon is hereditary.

In another experiment hybrid mice of the first genera tion of the same cross which had been allowed to bree completely at random were tested. A few young virgi females were picked out at random and ovariectomithe age of 2 months and treated similarly with gen. In most of these there was a variety of sponse in all mammæ, and a few mice showed the two tremes of the two original parents.

On another occasion mongrel mice were obtained from dealer in Liverpool, chosen because, so far as one knew, ere was no breeding of pure lines in that town and no ance of dealers there getting pure-line mice into their cks via experimental laboratories. Eleven white mice ot all albinos) were tested in the same way for their ammary-gland response to œstrogen. Again there was ariety of reaction. Some mammæ responded normally duct outgrowth, others showed a localised lobular-eolar response, and the mammæ in one mouse resemd the highly atypical response of the R3 strain in ality but not to the same degree. The existence of s capacity in some mongrel mice to respond atypically nts to selection of this quality in pure-line mice from ilar ancestors by inbreeding. It appears to be a ncidence that milk-borne-agent carrying capacity, erited susceptibility, and a peculiarity of response in e mammæ have been inbred together.

The inherited capacity for a localised atypical response ikes one at first as very unusual, but it is no more and less odd than a peculiar human trait—e.g., a facial pression or nose handed down from generation to neration while other qualities vary. The fact that a culiar response is localised, for example, in the half-d-half reaction of the first hybrid generation, indicates o a localisation of special sensitivity in parts of the mmary epithelium. It is not a function of the pituitary d. But for this tendency to localisation of response, might have been thought that the pituitary glands of e reactors had been stimulated by œstrogen alone to crete all the mammogens needed to produce it. Perhaps e data provided by the mice serve as a clue to ausation of cystic disease in the human subject.

MODE OF ORIGIN OF THE CYSTIC STATE

In comparing the exact method by which the cystic ate arises in human and rodent there are two remaining oblems: (1) the mechanism of distension; and (2) the istence of any evidence of variation in response to strogens in human mammary epithelium.

In rodents it is clear that distension is passive, due to pid secretion of a milky fluid before which walls of ucts and acini appear to give way. So far as my observaons have gone of the artificially created cystic states, e distending force operates locally; the effects of a llection of fluid at one place are not transmitted back. ecretion and proliferation of ducts and acini are active. pithelial hyperplasia within the lumen of the ducts as absent except in outgrowing ducts while they were nder the influence of œstrogen. Desquamation was rely seen in the absence of milk-borne agent.

In the human disease the view taken by Cheatle and utler (1931) was that distension was passive, especially reference to duct distension, and was due to a secreted uid. It was not inflammatory in origin. But they ought also that epithelial hyperplasia and desquamaon of epithelial cells played an essential part in opening p the lumens of acini and in breaking down partition alls between them. Nevertheless they state:

> "In some instances the peripheral ducts and acini which have undergone cystiphorous changes only lead into large dilated ducts which exhibit no indication of epithelial hyperplasia and no cause for their obstruction. Their dilatation is due to their passive distension induced by the fluid secreted by the diseaso situated at their periphery."

In one and the same specimen one may often see both pithelial hyperplasia with desquamation and distended ystic ducts. The relationship, if any, between these two tatic pictures is a matter of guess-work. They may not e stages in one process.

This discrepancy of observation and interpretation between the human and rodent conditions is the most important that has been found in the course of this comparison. It might be resolved by assuming a difference in reactivity of epithelial cells in different parts of the duct and acinar systems in humans and mice. Such a difference is reflected in the sites from which tumours of the breast arise. In the human subject, according to Cheatle and Cutler (1931) and to Muir (1941) and most other observers, proliferation and malignant epithelial change are almost invariably intraductal. In the mouse, according to Bonser (1945), the malignant change is acinar in origin. It seems probable that responsiveness to formative stimuli is more pronounced in acinus-forming cells in the mouse, whereas in the human duct epithelium and acinar epithelium are equally responsive to hormonal impulses and the duct epithelium is more so towards malignant proliferation.

VARIATION IN RESPONSE OF HUMAN MAMMÆ TO ŒSTROGENS

The question remains whether there is any evidence of individual variation among human subjects in response to œstrogens. Two types of mammary parenchyma have been described in girls at and after puberty. There is also some controversy over changes that may accompany menstruation. This controversy applies to both types of gland and does not concern the present problem. It seems to be the case that the developing ductule at the end of a duct or branching from it is most often a compact structure with small patent lumen, but Dawson (1934), Dieckmann (1925), and Ingleby (1942) have also described dilated ductules, which are referred to as infantile or immature. Ingleby has suggested that cystic disease may arise in a type of mammary gland originally immature in morphological type. When acted on by the functioning ovary, the ducts and tubules continue to grow and distend, and in course of time give rise to signs and symptoms in virtue of distension.

The condition which occurs in women in the middle period of life differs from the immature pubertal gland essentially in increased proliferation and distension of ductules accompanied by secretion. The relationship, shapes, and sizes of ducts and ductules are most revealingly displayed by the thick-slice method of Ingleby and Holly (1939). When preparations made in the same way of the infantile type of adolescent breast and of adult cystic disease are compared, their similarity is striking. Allowing for differences in magnification, many of Ingleby's illustrations resemble also the induced cystic state in mice (fig. 2).†

Cheatle and Cutler (1931) mention two instances of cystic ducts in infants, one localised, the other widespread. At this stage the mammæ are subject to the influence of maternal œstrogen.

Ingleby's (1942) interpretation of the origin of cystic disease differs from that of Geschickter (1945) in that it emphasises an individual difference in anatomical type of gland rather than the action alone of œstrogen and progesterone imbalance. The occurrence of localised cystic disease strongly favours Ingleby's interpretation, and so does all the evidence from experimental mouse pathology. Evidence of inheritance of cystic disease seems not to have been collected. Geschickter mentions three sisters affected by it.

SUMMARY

Human and experimental cystic disease of the breast are comparable.

Discrepancies exist in the interpretation of the way the cysts develop.

Both conditions are probably brought about by excess of œstrogen acting on mammary epithelium that responds atypically.

---

† All figures of mouse glands are photomicrographs of bulk stained whole mounts.

The decisive factor is not merely excess or imbalance of œstrogen but the nature of the parenchyma.

Cystic disease of the breast is an entity independent of mammary cancer.

It does not predispose to mammary cancer of mice when the cancer is activated by the tumour agent.

Its relationship to chemical carcinogens remains to be determined.

SYCOSIS BARBÆ

SEROLOGICAL TYPES OF STAPHYLOCOCCUS PYOGENES IN NOSE AND SKIN AND RESULTS OF PENICILLIN TREATMENT

B. C. Hobbs
B.Sc., Ph.D. Lond., Dip. Bact.

H. L. Carruthers
M.B. Sydney, D.T.M., Dip. Bact.

J. Gough

From the Emergency Public Health Laboratory and the Department of Pathology, Welsh National School of Medicine, Cardiff

It is recognised that the source of *Staphylococcus pyogenes* * causing sycosis barbæ may be a focus present in some part of the upper respiratory tract, particularly the nose and even the apparently healthy nose. Burrows et al. (1945) showed that relapses of sycosis barbæ were reduced by application of penicillin cream to the anterior nares as well as to the infected skin of the beard area. They emphasised the necessity for concomitant treatment of any active manifestation of sepsis, such as nasal discharge, blepharitis, and otitis media or externa. There does not appear, however, to have been any previous attempt to correlate serological types of *Staph. pyogenes* causing the lesion with those isolated from the patient's own upper respiratory tract.

The objects of the present investigation were (1) to study the effect of treatment of sycosis barbæ with penicillin cream, and (2) to compare serologically the strains of *Staph. pyogenes* isolated from the lesions with those found in the nose, eyes, or ears of each patient. The subdivision of *Staph. pyogenes* into serological types has enabled us to use the bacteriological findings in explaining cure, relapse, or recurrence of infection and failure of penicillin treatment.

PROCEDURE

Bacteriological.—On first examination swabs were taken not only from the skin lesions but also from the nostrils and throat, and (if they appeared to be infected) the ears and eyes. Further swabs, particularly from the nose, were taken at intervals during treatment and immediately before the patient was finally discharged. All swabs were cultured on two blood-agar plates, one of which contained 1/500,000 gentian violet, to disclose the presence of hæmolytic streptococci.

Coagulase-positive colonies of staphyloc
selected by using the slide coagulase test
Graves et al. 1943); and any colonies showin
reactions were re-examined by the tube test (
At least two colonies were subcultured for typ

Serological typing was carried out by Co
agglutination technique (Cowan 1939), using
instance the set of sera, absorbed and u
suggested by Cowan. These were supplem
absorbed sera prepared from strains differing an
from Cowan's types I, II, and III and isolated
and Keogh (1940) and by one of us (B. C. H.)
nomenclature has been adhered to as a basis,
strains which did not fit clearly into one or o
types were identified by using these additiona
sera.

Penicillin sensitivity tests by both plate
methods were carried out on the infecting
Staph. pyogenes when they were first isolated
time to time during treatment.

Treatment.—Cream containing penicillin
per g. in 25% or 30% neutral 'Lanette w
water (Gough et al. 1945) was issued to all pa
instructions to apply the cream to the face
morning or oftener if desired, and to insert the
the nose with a throat swab and to inhale
An alternative suitable cream was the same con
of penicillin in lanette wax sx 18%, glycerin
water 75%. Penicillin cream as described was
containing either 1·0% or 1·5% 'Phenoxe
preservative against contamination with gra
bacilli and moulds (Gough et al. 1944).

Fresh penicillin cream was issued at weekl
nightly intervals until the facial lesions had c
the infecting strain had disappeared from
If the infecting strain persisted, treatment i
was stopped after two or three months. On
patients were told to report immediately s
lesion recur. If profuse nasal carriage of the
strain of *Staph. pyogenes* was suspected to be
with some pathological condition of the upper r
tract, the patient was referred to the ear, nose,
department for investigation and treatment.

RESULTS

Staph. pyogenes was isolated, usually in pur
from the facial lesions of each of the 23
investigated.

Table I shows the degree of correlation
between the strains of *Staph. pyogenes* foun
lesion and in the nose of 19 patients whose str
typed. In each of the 17 patients in whom stap
were found in the nose the strains were of
serological type as those in the skin lesions: 1

Staph. pyogenes present—not examined serologically; —, no *Staph. pyogenes* found; H.S., hæmolytic streptococci.

rted a very slight recurrence while he was ill in bed with vere cold, but the few spots cleared at once with penicillin m. Nose swabs taken at the end of the investigation wed *Staph. pyogenes* of a type different from that causing original infection. Cases 17, 21, and 22 have so far not orted at the clinic after the primary lesions had healed.

roup B consists of 4 patients in whom relapse took place, term "relapse" being used to indicate reappearance of s due to the same type of *Staph. pyogenes* as caused the cal skin infection. Of these patients, 3 were re-examined months after the relapses had been treated: 2 had ained clear of infection; case 23 showed no *Staph. pyogenes* the nose, case 1 showed *Staph. pyogenes* of a type different n that originally isolated from lesion and nose. Case 5 s suffering from a further relapse at the time of the follow-examination, and swabs from lesion and nose showed the e type of *Staph. pyogenes* as had caused the original ction. Cases 1 and 5 had had blepharitis for twenty rs and six years respectively; they reported persistence the condition in spite of treatment, though there was provement in case 1. The fourth patient (case 2) did not ear for re-examination after the relapse had cleared.

roup C includes 2 patients in whom sycosis recurred e to a type of *Staph. pyogenes* different from that which sed the original infection. Case 8 was interviewed five nths after the recurrence had cleared. He had remained e from infection during this period, and nose swabs revealed ph. *pyogenes* of yet a different type from those found in the ions and nose on the two previous occasions.

roup D illustrates the only case in which the infecting anisms were penicillin-resistant and the treatment failed. peated attempts were made to clear the infection by inject- as much as 10,000 units of penicillin locally into a large ion on the chin which had developed into a pocket of pus, little improvement was noted. Table III illustrates the gress of 3 cases representative of the first three groups.

The clinical improvement was usually immediate and amatic, as described by Roxburgh et al. (1944) and hers, but it seemed advisable to continue treatment til the nose was clear of staphylococci. In one tient (case 7) who had had sycosis for fifteen years ere was a surprising improvement in the texture of e skin when the infection was controlled. Another ase 1) could shave properly for the first time for fifteen ars and said that within a few days of the start of eatment he had the best shave for twenty years. When sociated blepharitis was treated, eyelashes grew and ayed in for the first time for years. Relapse came as a tter disappointment to a high proportion of the patients. hese relapses, however, usually responded to a second urse of treatment. Some of the relapses occurred uring treatment, probably owing to inactivation of e penicillin cream by the development of acid in the utoclaving of lanette wax SX (see Gough et al. 1945).

DISCUSSION

The bacteriological findings in sycosis barbæ show that the same types of *Staph. pyogenes* occur in the skin lesion and in the nose, and they provide further evidence to support the view that the beard becomes infected and reinfected by nasal discharge, by the hands of a persistent nasal carrier, or by the handkerchief. A study of the therapeutic effect of penicillin on these cases shows that a proportion can be cured, provided the infecting strain is also eliminated from other sites, such as the nose. Roxburgh et al. (1944) report good results with penicillin, but in one case there was not even temporary cure, probably owing to continued reinfection from nasal discharge. Du Boulay (1946) recorded improvement, but with some persisting infection in 5 cases of sycosis treated with penicillin cream; no mention is made of treatment of nose or other source of infection. Treatment must be directed to this end; but, even if elimination of the infecting strain is successful, it is no guarantee against relapse due to the same type or against recurrence of sycosis due to infection by a different type of *Staph. pyogenes*. In those who relapse with the same type, it is not possible to say whether the organisms persisted in the nose or whether the patient was reinfected from without. The possibility of persistent skin carriage—e.g., in the hands—of the infecting strain must also be considered; no attempt to determine or control this possible source of infection was made in the present series. Failure is also to be anticipated if the organism is penicillin-resistant. This was so in 1 of our 19 cases.

TABLE II—PERIODS OF TREATMENT WITH PENICILLIN CREAM NECESSARY TO CURE PRIMARY LESION AND RELAPSES

Case no.	Duration of infection (years)	Time to clear primary sycosis (weeks)	Interval to first relapse (weeks)	Time to clear first relapse (weeks)	Interval to second relapse or reinfection (weeks)	Time to clear second relapse or reinfection (weeks)	Remarks

	Nov. 20, 1945	..	—	—	..	..	Face and nose clear ; patient discharged ; intermittent 31 weeks ; one relapse and one rence cleared with penicillin cream applied to and nose

—, no *Staph. pyogenes* found.

No serious ill effects were observed from the penicillin cream or the penicillin and phenoxetol cream in this series, but penicillin contact dermatitis may also be the cause of failure in treatment, and in some of the patients treatment had to be suspended temporarily because of reaction to penicillin. In a case of seborrhoeic dermatitis in which there was secondary infection with *Staph. pyogenes*, local treatment with penicillin cream produced œdema and erythema, and systemic injections produced a generalised rash.

It is not suggested that penicillin in the form of cream is necessarily the best means of treating the nose, but it was convenient to try it and thus keep the procedure simple. All those treated were outpatients, and it was impossible to provide an alternative method. Sprays or snuffs, however, may prove more effective.

SUMMARY AND CONCLUSIONS

Penicillin cream is effective in curing sycosis barbæ, provided the infecting strain of *Staph. pyogenes* is sensitive to penicillin.

The same serological type of *Staph. pyogenes* is usually present in lesion and nose, and failure to eliminate the strain from the nose may lead to relapse. The should therefore be treated at the same time as the lesions.

Penicillin cream is generally effective in clea *Staph. pyogenes* from the healthy nose unless the str is resistant to penicillin. Reinfection of the nose by same or a different type of *Staph. pyogenes* may be follow by a recurrence of the skin lesion.

The penicillin sensitivity of all infecting strains *Staph. pyogenes*, both in the lesion and in the n *should be determined.*

We wish to thank Dr. V. D. Allison for much encourage and helpful advice, and Dr. B. Thomas and Dr. T. Phillips assistance with the clinical side of the work.

TENSIVE TREATMENT OF KALA-AZAR ITH SODIUM ANTIMONYL TARTRATE

A. R. D. ADAMS M.D. Lpool, M.R.C.P.
D. R. SEATON M.B. Camb., M.R.C.P.

From the Liverpool School of Tropical Medicine

lves and Blair[1] have described a treatment for stosomiasis by the intensive administration of ium antimonyl tartrate. Though this drug has largely n supplanted in the treatment of kala-azar by various tavalent antimonials, or by the diamidines, we ided to try Alves and Blair's treatment in this disease. ing the past year six cases of Indian kala-azar have been treated.

he preparation used was a sterile 2% solution of um antimonyl tartrate, obtained in ampoules from ns Medical Supplies Ltd. The total dosage for each ent was about gr. 1 per 12 lb. of body-weight, in intravenous injections given at three-hourly intervals, lly at 9 A.M., noon, and 3 P.M., on two successive days. appropriate dose was made up to 15 or 20 ml. with mal saline and injected intravenously through a fine dle, a minimum of 5 min. being taken over the ction. Toxic symptoms as a result of the injections e not severe. Most of the patients had paroxysms oughing, lasting about a minute, immediately after or more of the injections, and in a few instances the ghing was followed by vomiting. Case 5 developed ric jaundice two days after the injections, but this ed in the course of a fortnight.

se 1.—An Indian seaman, aged 35, was admitted to pital on April 6, 1946, complaining of headache, fever, loss of weight during the previous month.

n admission : liver and spleen both enlarged (2 finger-dths); weight 6 st. 12 lb.; anæmia (red cells 3,200,000 c.mm.) and slight leucopenia (white cells 4200 per m.); formol-gel test strongly positive; Leishman-Donovan ies in films of the sternal marrow; marrow cultures tive.

reatment and Progress.—Patient was given sodium anti-nyl tartrate gr. 8 intravenously in six equal doses on il 16–17. Temperature, which had been ranging between F and 104°F, fell to normal on day after treatment continued so until his discharge, apparently well, on y 27. Weight was then 7 st. $9^1/_2$ lb., red cells 4,800,000 and ite cells 4150 per c.mm. Spleen no longer palpable, and r only just so. Formol-gel test showed slight opacity no solidification.

atient returned to India and was lost sight of, presumably ed of his infection.

Case 2.—An Englishman, aged 29, had served in the Army India and Burma from 1942 to October, 1945. In March, 6, he had reported sick, in Germany, with occasional vering attacks, loss of weight, and abdominal swelling of e weeks' duration. Leishman-Donovan bodies had been nd on spleen puncture. He was sent to Liverpool for atment and was admitted to hospital under our care on il 11, 1946.

On admission : abdomen distended by enlargement of liver d spleen to level of umbilicus; weight 8 st. 3 lb.; anæmia d cells 2,900,000 per c.mm.) and leucopenia (white cells 0 per c.mm.); formol-gel test strongly positive.

Treatment and Progress.—Patient was given sodium timonyl tartrate gr. 10 intravenously in six divided doses April 16–17. Temperature, which had been rising in e evenings to 99–101°F, fell to normal a week after the jections, and apart from four small rises remained so for weeks.

During that time there was no reduction in size of liver or leen, and formol-gel reaction remained strongly positive. eight increased to 9 st. 4 lb., red cells to 4,200,000 and white lls to 2500 per c.mm.

By June 28 he was again febrile, and cultures of his sternal arrow for leishmania were positive.

On July 4–5 he was given sodium antimonyl tartrate gr. $10^1/_2$ in six doses. His temperature became normal after four days; it remained so until Aug. 28, when he developed lobar pneumonia, which was treated with sulphadiazine.

On his discharge from hospital, apparently well, on Aug. 25 his weight was 9 st. $12^1/_2$ lb., red cells 4,100,000 and white cells 8500 per c.mm. Spleen and liver much smaller but still enlarged (2 finger-breadths). Smears and cultures from his sternal marrow were negative for leishmania.

Patient then returned to civil life and has remained apparently well to date. He may therefore be assumed to be cured of his infection after the second course of treatment.

Case 3.—An Indian seaman, aged 45, was admitted to hospital on April 27, 1946, with ten days' history of fever and malaise, accompanied by severe headache and pain in the loins.

On admission : liver not palpable, but spleen could just be felt; weight 7 st. 13 lb. Anæmia (red cells 3,200,000 per c.mm.) and leucopenia (white cells 4000 per c.mm.); formol-gel test negative; Leishman-Donovan bodies in sternal marrow films. Temperature, which was at first remittent and later intermittent, fell to normal before treatment.

Treatment and Progress.—Patient was given sodium antimonyl tartrate gr. 11 in six doses on May 26–27. He was discharged from hospital, apparently well, on June 18, when his weight was 8 st. $9^1/_2$ lb., red cells 4,800,000, white cells 6500 per c.mm. Spleen no longer palpable. Patient was lost sight of but was regarded as presumably cured of his infection.

Case 4.—An Indian seaman, aged 42, was admitted to hospital on July 30, 1946, with two weeks' history of intermittent fever. He was afebrile on admission, and remained so throughout his stay.

On admission : weight 6 st. 0 lb.; spleen enlarged (3 finger-breadths) and liver just palpable; anæmia (red cells 2,100,000 per c.mm.) and leucopenia (white cells 3400 per c.mm.); formol-gel test positive; Leishman-Donovan bodies in sternal marrow films.

Treatment and Progress.—Patient was given sodium antimonyl tartrate gr. 8 intravenously in six doses on Aug. 9–10. He was discharged, apparently well, on Oct. 8, when his weight was 7 st. 8 lb., red cells 4,100,000 and white cells 4900 per c.mm. Spleen just palpable. Films and cultures of sternal marrow were negative for leishmania. Patient was lost sight of, apparently cured of his infection.

Case 5.—An Englishman, aged 30, had served in the Army in India and Burma from June, 1942, to November, 1945. He was admitted to hospital on Sept. 5, 1946, with nine months' history of intermittent fever and of loss of weight.

On admission : liver and spleen much enlarged (a hand's breadth); weight 11 st. 8 lb.; anæmia (red cells 3,600,000 per c.mm.) and leucopenia (white cells 1450 per c.mm.); formol-gel test positive: Leishman-Donovan bodies in sternal marrow films.

Treatment and Progress.—Patient was given sodium antimonyl tartrate gr. 13 in six injections on Sept. 17–18, after which his temperature, which had been rising irregularly to 99–100°F, became normal in six days.

Patient was discharged from hospital, apparently well, on Nov. 28, when the formol-gel test was negative, and smears and cultures of sternal marrow were negative for leishmania.

When last seen as an outpatient, on March 15, 1947, his weight was 12 st., red cells 5,500,000 and white cells 5600 per c.mm.; spleen no longer palpable, and liver only just so. He may be regarded as cured of his infection.

Case 6.—An Englishman, aged 25, had served with the R.A.F. in India for the three years ending August, 1945. He had fallen ill in August, 1946, with fever, headache, and occasional vomiting, and had been admitted to Blackburn Royal Infirmary, where he had remained, apart from one short break, until Jan. 18, 1947. He was then transferred to Liverpool Royal Infirmary. In Blackburn he had had two courses of 'Neostam' (2·7 g. in all) without much benefit. On Jan. 13 Leishman-Donovan bodies had been found in the splenic pulp.

On admission under our care: liver and spleen enlarged (2 finger-breadths and a hand's breadth respectively); weight 8 st. 2 lb.; anæmia (red cells 2,400,000 per c.mm.) and leucopenia (white cells 1400 per c.mm.); formol-gel reaction positive.

---

[1] Alves, W., Blair, D. M. *Lancet*, 1946, i, 9.

Treatment and Progress.—Patient was given sodium antimonyl tartrate gr. 10 in six injections on Feb. 5–6. This produced no effect whatever on his temperature, which had been rising daily to 100–102°F since admission. Blood-count remained unaltered, and on Feb. 19 a culture of leishmania was recovered from the sternal marrow.

Patient was subsequently successfully treated with pentamidine.

DISCUSSION

Of the six cases treated with sodium antimonyl tartrate one showed no response whatever to the drug, and another relapsed after a short period of clinical improvement, but was cured by a second course. Of the remaining four cases one was observed for six months after treatment and was certainly cured. The three other men were Indian seamen and returned to their occupation three, six, and eight weeks after treatment. That they were probably cured is suggested by the disappearance or diminution of the signs and symptoms of the disease during the period of observation, but the possibility of a subsequent relapse cannot be wholly excluded.

The results of intensive antimony treatment in these few cases do not compare favourably with those obtained with 'Neostibosan' or with 'Urea stibamine' in Indian kala-azar, a full course of either of which produces a cure-rate of 90–95%,[2] or with the aromatic diamidines. The method can at present be recommended only where many cases have to be treated rapidly, and the cost of treatment is an important consideration. The duration of treatment by the method we have used was two days as against eight days (neostibosan), twelve days (pentamidine), and thirty days (urea stibamine), and the cost of the drug was less than that of any of these.

GAUCHER'S DISEASE WITHOUT SPLENOMEGALY

MARGARET E. MORGANS
M.B. Lond., M.R.C.P.
ASSISTANT, MEDICAL UNIT, UNIVERSITY COLLEGE HOSPITAL MEDICAL SCHOOL, LONDON

GAUCHER'S disease has been defined as a rare disease characterised pathologically by the deposition of kerasin in the reticulo-endothelial cells and clinically by splenomegaly, hepatomegaly, hypochromic anæmia, and leucopenia. Among other less constant findings are pallor, with a uniform brownish discoloration of the skin, pigmented pingueculæ, brown pigmentation of the shins, thrombocytopenia, and hæmorrhages, and deposits in the bones, leading to deformities, with local and referred pains. The disease is usually detected in childhood by the finding of a greatly enlarged spleen. Though admitted to be both congenital and familial, it is not generally considered to be hereditary. Its course is chronic, but survival beyond middle age is unusual. Death is usually due to intercurrent infection, but a few patients die from progressive anæmia or from thrombocytopenic purpura.

The present series of cases in one family is remarkable in three ways: (1) splenomegaly was absent; (2) a hereditary tendency was evident; and (3) the older patients have survived in active life to advanced age.

CASE 1.—Patient was a doctor, aged 67, of Welsh descent. From childhood his pallor had attracted notice, and in his early years he was always given iron. When he was a medical student his colour excited repeated comment, but his blood contained Hb 90%.

His present complaint was that during the previous two years, while exercising with the Home Guard, he had become more and more inconvenienced by shortness of breath. He had also noticed giddiness after sudden changes of posture.

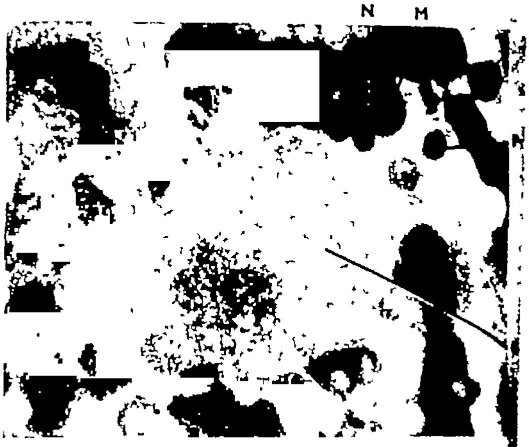

Fig. 1—Photomicrograph of sternal-marrow smear in case I
G, Gaucher cell; M, myelocyte; N, normoblast; P, polymor

When he consulted another doctor, his brownish pallor attracted attention, and a blood examination showed 60%, white cells 9000 per c.mm.

Iron was prescribed but had no effect, and patient referred for investigation of the anæmia. The past his viewed in retrospect appears now to have been signific For thirty years the patient had had pains in the low dorsal and lumbar regions and over the left hip and outer side of the left thigh. These he had regarded treated as sciatica. He had had a similar pain in the of the right arm. He had observed that all his bones unduly tender; if he knocked them, a peculiarly nau pain followed and persisted for some time, especially right radius. He was also said to have had renal colic years ago and to have passed "gravel"; but no stone ever demonstrated. Apart from these complaints he had bronchitis during the last five years; one attack sufficiently severe to be classed as bronchopneumonia.

On examination the patient was a slight brisk rather man in the late sixties. His skin was uniformly pale with a slight brown tinge. Pigmented pinguecula present in both eyes, but they were not notably diff from those often seen in hepatic disease. The sclerotics otherwise normal in colour. The tongue was normal rather pale. A pronounced "cobbler's breast" defo was present. Examination of the heart revealed no ab mality save a soft apical systolic murmur. The blood-pre was 170/90 mm. Hg; the limb arteries were rather tortu but the retinal arteries were normal. Showers of fine r heard at the bases of the lungs, persisted after cough The central nervous system showed no abnormality. the abdomen the liver was felt easily from one to two fing breadths below the costal margin; it was firmer than norm but smooth, and the edge was sharp, elastic, and regu The spleen was not palpable, nor was the splenic dull increased. There was no œdema of the ankles, no ascit and no collateral venous circulation. There was no pigmenta tion of the shins.

Investigations.—Blood: Hb 70% (Haldane), red cel 5,000,000 per c.mm., colour-index 0·7, mean cell diam 7·2 μ, white cells 7000 per c.mm. (polymorphs 58%, lym cytes 33%, monocytes 6%, eosinophils 3%), conside anisocytosis and hypochromia, no polychromasia, no nucle red cells; sedimentation-rate 8 mm./hr.; van den reaction direct negative, indirect 0·4 mg. per 100 c *Urine:* a trace of albumin; no other abnormalities; cult sterile. *Sputum:* no tubercle bacilli present. *Fracti test-meal:* resting juice 16 c.cm.; free acid rose to 30 c in 1½ hours; total acid rose to 60 c.cm. in 1½ hours. St one specimen contained occult blood, but the next contained none.

Radiography: chest showed no evidence of local disease; right and left domes of diaphragm at normal leve renal tract showed two faint opacities in front of the kidney, possibly a calcified gland or gall-stones; t showed gross alveolar absorption; barium meal showed abnormality.

The cause of the anæmia thus still remained obs so a *sternal puncture* was done to exclude, if possible,

---

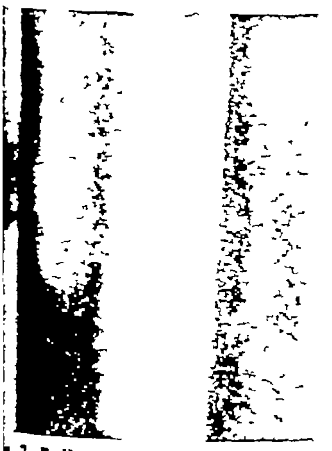
plastic anæmia, an aleukæmic leukæmia, or other disease of reticulo-endothelial system. Stained films of the marrow tained Gaucher cells. The differential count of 500 cells as follows:

	%
Polymorphs: adult	12·7
band	4·3
young	6·2
Eosinophils	1·2
Myelocytes	25
Eosinophil myelocytes	2·7
Premyelocytes	7·7
Myeloblasts	3
Lymphocytes	8·6
Monocytes	1·8
Normoblasts	3·2
Erythroblasts: acidophil	5·9
polychromatophil	3
basophil	15·7
Pro-erythroblasts	0·3
Plasma cells	0
Smudge cells	0·3
Gaucher cells	0·4

$$\frac{\text{Myeloid cells}}{\text{Nucleated red cells}} = \frac{2 \cdot 5}{1} \quad \left(\text{normal } \frac{8}{1} \text{ to } \frac{2}{1}\right)$$

The Gaucher cells (fig. 1) measured 30–80 μ. The cytosm showed the typical fibrillary structure as described Pick (1933). The cells varied in shape, but most of them re not stretched, as described by most workers in the eous form of the disease. The nuclei were commonly single, usually eccentric, and endothelial-like. The cells did not stain with Scharlach R. No crystals were seen with polarised light. A film was fixed in formaldehyde, heated in boiling water, and then again examined for optical activity, but no optically active substance was seen. The prussian-blue reaction was negative.

In view of the pains in the long bones and the detection of Gaucher cells in the sternal marrow it was decided to radiograph the skeleton. A small translucency in the ft parietal bone, two large ones in the right radius, and one the left radius (fig. 2), all typical of Gaucher's disease, were und. There were some doubtful translucencies in the upper alf of the humerus, and some in the bodies of T11, T12, and L1 ertebræ. These translucencies were thought to represent posits of Gaucher tissue. Osteo-arthritis was present in the kn.



2—Radiogram of radius and ulnar in case 1, showing typical translucency at lower end of radius (marked by arrow).

Case 2.—A soldier, aged 23, on active service, the son f case 1. A congenital abnormality of the heart was detected n routine examination in America, but the patient had no ability and no symptoms. He had a sallow complexion ut was not anæmic. He also had the "cobbler's breast" eformity noticed in case 1. There was slight enlargement f the heart, with an apical systolic murmur. Neither liver or spleen was palpable. He had no pingueculæ or pigentation of the legs. Radiography showed a definite transucency in the upper part of the shaft of the left humerus. he remainder of the skeleton was normal.

Case 3.—A schoolgirl, aged 14, the daughter of case 1, as very pale but was not clinically examined. She had no mptoms. Radiography showed typical translucent areas in he lower end of the femur (fig. 3).

Case 4.—A schoolboy, aged 12, the son of case 1, also had sallow complexion but was not anæmic. No enlargement f liver or of spleen. No pingueculæ and no pigmentation f legs. No "cobbler's breast" deformity. Radiography howed a doubtful translucency in the lower end of the etaphysis of the left humerus. This was not thought to e definitely diagnostic of Gaucher's disease.

FAMILY HISTORY

A family tree is shown in fig. 4. Case 1's maternal grandmother had been pale, with a peculiar brown skin; otherwise she had appeared well. She died from cerebral thrombosis at the age of 75. Her husband had been healthy and normal in appearance. Case 1's father died at 66, from carcinoma of the colon, and his mother at 54 from cerebral hæmorrhage. All her life she had been remarkable for her pallor. She had had intractable menorrhagia, which, if she had Gaucher's disease, might possibly have been caused by a thrombocytopenia. Case 1's maternal aunt, also remarkable for her sallow complexion, died at 69 from diffuse purpura after taking medicine, possibly iodine, prescribed by her doctor. If she had Gaucher's disease, this purpura may also have been caused by thrombocytopenia. Case 1's maternal uncle died as a baby from "brain-fever" (infantile cases of Gaucher's disease may run an acute downhill course with symptoms referable to the nervous system). Case 1's elder sister is pale, with a café-au-lait complexion. His younger sister is pale but less sallow than the elder; her daughter has a very clear complexion, but the elder sister's son is very pale. Case 1's three children are cases 2 and 3, who appear to have Gaucher's disease, and case 4, who is suspected of having it. His wife is an Austrian refugee, family history unknown.

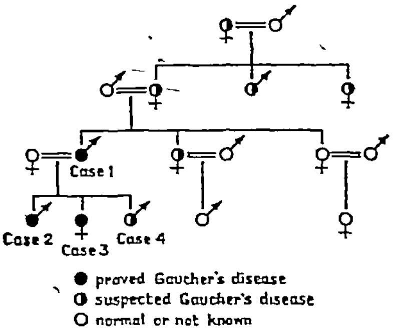


Fig. 4—Family tree showing proved and suspected cases of Gaucher's disease.

DISCUSSION

Hitherto it has been generally agreed that splenomegaly is an invariable and necessary feature of Gaucher's disease. The absence of splenic enlargement from the present cases is therefore of particular interest. In cases 1 and 2 the spleen was not palpable and there was no increase of splenic dullness. Case 3 could not be examined clinically, but it can be assumed that the spleen was at least not conspicuously enlarged, or it would have been detected when she was medically examined on other occasions. I have found only one case in the literature in which there was no splenic enlargement (Erf 1938). This patient complained of pains in the limbs; bone translucencies were seen on radiography, and Gaucher cells were seen in the marrow. It seems therefore that, besides

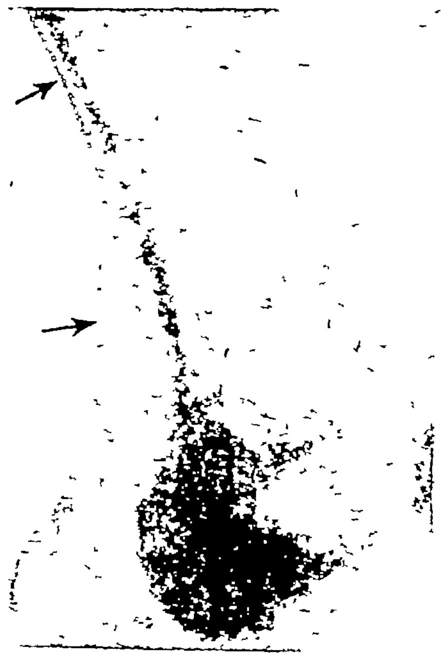

Fig. 3—Radiogram of lower end of femur in case 3, showing typical translucencies (marked by arrows).

the familiar form with splenomegaly and the acute infantile form with the involvement of the central nervous system, there is a third type of Gaucher's disease without splenomegaly. This type may be relatively common, as its only symptoms are those of a mild anæmia. In such cases the diagnosis can only be made with certainty during life by finding Gaucher cells in the bone-marrow.

Cases of Gaucher's disease which are first diagnosed after the second or third decades are rare enough to arouse comment. Horsley et al. (1935) describe a case first detected at the age of 47. Mandelbaum et al. (1942) claim that their case is of interest because it was not recognised before the fifth decade. Wechsler and Gustafson (1940) describe a case in which the disease was first detected at the age of 68. Case 1 reported here was not detected until the age of 67. The family tree (fig. 4) shows that Gaucher's disease is suspected in some other members of the family who lived an active life until well over middle age.

There is considerable divergency of opinion about whether Gaucher's disease is congenital, familial, or hereditary. Pick (1933) states that it is congenital and familial, and that in about a third of the cases several members of one generation are affected, but that the disease is limited to that generation. Hoffman and Makler (1929) state: "in no series of children did either of the parents suffer from the disease, nor has it been transmitted from any adult to a child." Most workers seem to agree with these views but there are a few notable exceptions.

Bloem et al. (1936) report cases of Gaucher's disease in two families which had an apparently normal common grandfather. His son by his first wife had an enlarged liver; one of this son's seven children was a proved case of Gaucher's disease with splenomegaly, and two were suspect. By his second wife he had an apparently normal son; among the latter's nine children were one proved case and two suspected cases of Gaucher's disease. Anderson (1933) reports that an apparently normal male had nine children, four of whom had splenomegaly. Two of these were proved cases of Gaucher's disease, and the two other children were remarkable for their pallor. The paternal grandmother and her two sisters were said to have had large abdomens and brown skin and to have died from a similar illness.

Pachman (1938) refers to possible hereditary transmission but gives no pedigree.

Bychowski (1911) described a family in which a father and three children had splenic enlargement and probably had Gaucher's disease.

Plehn (1909) observed Gaucher's disease in a man and his daughter.

The present case 1 has been proved to have Gaucher's disease, and two of his three children provide radiological evidence of the disease. Other members of the family, from their histories and description, may well be affected but were not available for investigation.

It thus appears from the published records of previous cases that there are reasons for considering that Gaucher's disease may be hereditary, provided it is accepted that the condition may be transmitted by an apparently healthy person. The importance of the present series in this respect is that it reveals that Gaucher's disease is compatible with a long healthy life and can exist without those visceral enlargements which have previously been considered one of its invariable features. It is therefore possible that those apparently healthy subjects, who are suspected of having transmitted the disease, may in fact have been affected by the condition in the form here described.

SUMMARY

A family affected by Gaucher's disease, but in whom none of those affected show splenomegaly, is described. The diagnosis was made by the detection of Gaucher cells in the bone-marrow and by the presence of typical radiological lesions in the bones. The family suggests that in this series the disease was not congenital and familial but also hereditary. All or were leading, active lives, and in one case the was first made at the age of 67 years.

THE DROPSIDE COT IN HOSPITAL

William Napier
M.D. Glasg.
PHYSICIAN-SUPERINTENDENT, SHIELDHALL FEVER HOSPI
GLASGOW

It is a time-established custom to nurse young childr in hospital in dropside cots. Enclosed in one of th cage-like structures each newly admitted patient pe at his neighbours through iron bars, and displays fre fulness and homesickness that may well be related t the restlessness and fear so often shown by wild anim in captivity. As the days pass, apprehension and rese ment gradually give place to indifference, followed children, if not in animals, by a growing interest in is going on round them.

By the time he is convalescent the child is no afraid of his surroundings, and within certain limits age and vitality regards his cot as the ideal play. The active yearling, unless held back by a "restr will pull himself up by grasping the side of the cot travel round it, or lean on the rail and gaze at the flo while happily exercising his lower limbs. Even under possible vigilance he may topple over; and, thoug serious injury rarely results from such a fall, the dang cannot be ignored.

Manufacturers have attempted to reduce the risk making the sides of their cots taller. Thus the eff parapet in the oldest cots in this hospital, a style regarded as obsolete, measures only 12 in., and in most modern type 17 in. Even this, however, is quate protection, being little more than half the he the year-old child, who can add to his stature by stan on his pillow. Another modification has been the spacing of the vertical bars, from $5^{1}/_{2}$ in., which a baby to push his head between them, to 4 in. or less.

On children past the toddler stage the dropside cot has little or no restraining influence, but serves to stimulate the climbing instinct. Boys enjoy t thrill of going over the top to recover a toy or merely an outlet for high spirits. Girls, usually more decorous, soon learn how to undo the so-called safety catch may attempt to lower the cot-side at the risk of a br forearm.

EFFECTS ON NURSES

As regards the nurse, the effect of the closed cot on subconscious mind must surely be that of frustration. Between her and her patient there is a barrier, removal and replacement of which many times a day entail no little inconvenience and loss of time. She needs at least one hand free for this purpose; so basin or tray she is carrying must first be set down, in all likelihood there is no convenient table or chair to receive it. Even in the lowered position the cot-side may be a hindrance to her work. In a modern type of cot it definitely interferes with bedmaking, and I often seen nurses balanced on one foot while with e they depress the top rail out of the way of the bed- hes. Some find it easier to disarticulate the side of cot completely before tucking in the blankets.

ilure to close the cot when leaving the patient has erto been regarded as a cardinal sin. In practice an omission is rare, but failure to secure the cot- properly is a common and subtle danger, for the t pressure is then liable to send it clattering down, an almost guillotine effect on any projecting limb.

he amount of energy expended in closing a series ildren's cots is not generally realised. Increase in height of the cot-sides has added to their weight; in ost modern type of cot here each weighs 17½ lb. This derous mass has to be raised vertically through 18 in., the top rail a final position of 44 in. from the floor. the nurse of average height little or no stooping is ssary, and the load falls almost entirely on the cles of the arm and shoulder girdle. The lift is efore an awkward one and when repeated a number imes imposes no small strain on the adolescent girl. ward of twenty cots, three rounds of bedmaking— ery conservative estimate of the 24 hours' routine h leaves out of account the many casual openings cot for feeding, &c.—entail in this respect alone expenditure of 3150 foot-pounds of energy, the total s lifted weighing almost a ton.

he opening and closing of the dropside cot is an ration which cannot be done quietly, and in a busy d the clang and clatter of metal can be almost con- [illegible]. It is common to see a drowsy or sleeping start convulsively as his cot is opened, and the sleep of older children is not always proof against ightly disturbance. In a fever hospital it is often ssary to accommodate adults in the same ward as cases," and to them the noise can be very trying day and almost intolerable by night. But the nuisance ot confined to the children's ward; it will penetrate ed doors and be felt all over a hospital block.

REMOVAL OF DROPSIDES

Thinking of these things led me inevitably to question ether the dropside is really necessary. The answer ed obvious enough: for any child aged over 3 years not mentally defective or delirious it is not. In ing this belief into practice I expected some opposi- from my ward sisters, and was not disappointed. The gestion that they leave in the open position the cots children between the ages of 3 and 8 years (7 years is usual age of transition to a full-size bed, but lack of accommodation may necessitate somewhat older ients being nursed in cots) evoked a chorus of dis- proval: "The cots are so untidy like that." "The ered sides interfere with floor sweeping." "We shall ver be able to keep the children in their places." Who is to be responsible when they fall out?"

The first two objections, both reasonable, were met by ing the cot-sides removed altogether and stored. e third contingency did not arise: occasionally a ld did leave his bed, but not more often than formerly, very much more safely. And no child at this stage out. It was soon found possible to give the same edom to children of 2½ years, and later, with some eptions, to those of 2 years.

The infant patient next claimed attention. There be general agreement that the hospital type of cot easuring 4 ft. 6 in. by 2 ft. 6 in. is far too large and ewise unsuitable for the baby of 6 months or less. whom the smaller domestic pattern or the cradle form ng from upright supports is more appropriate. Pro- sion of such special types, however, inevitably limits commodation to the youngest age-group, and in an fectious-diseases hospital accepting children of all ages is inexpedient to have any but a large size of cot. nts under 6 months old can be nursed in any case perfectly safely without the dropside, and it is now the practice here to do so. Admittedly there is a bias against it. Parents do not like to see their children apparently in danger of falling, and nurses to some extent share their feelings. When it is pointed out, however, that the baby, no matter how actively he moves his limbs, cannot alter his position, their apprehensions are allayed.

At the age of 6 months the child enters the most difficult period as regards control. He soon learns to sit up, a position which makes it possible for him to roll out of the open cot. Fixed sides some 6 in. high would now be ideal, but they are not on the market, and the dropside becomes a necessity. A few months later he may tend to stand upright, and when this happens he is no longer safe even in the closed cot. Many children at this stage of development need to wear a restrainer—i.e., a safety belt with tapes for attaching to the framework of the cot. Properly applied it is a harmless and very necessary article in a children's ward, allowing considerable liberty of movement, but the tapes must be strong and well tied to prevent breakage or self-release. It is wise to avoid any form of restraint, especially in the acutely ill child, whenever possible. My opinion is therefore that within the age-group 6 months–2 years both sick and convalescent children who show no inclination to stand upright should be nursed in the closed cot without further precaution. For those requiring mechanical restraint, and this may include some over 2 years, the dropside becomes redundant and should be dispensed with.

RESULTS

For several months these principles have been tested throughout this hospital, all cots, with the exceptions mentioned above, being left open. The benefit is apparent in every ward, particularly in the diphtheria and scarlet-fever pavilions, where most of the children are over 2 years old. The absence of metallic noise creates in these wards a hitherto unobtainable atmosphere of quiet. Though proof is still lacking of a decline in fretfulness among new arrivals, there is no doubt of the preference of young patients for the open cot; they enjoy being treated as little adults and, now that they are used to it, take no undue advantage of their freedom. Any threat to close a cot is looked on by its occupant as a punishment. Only two fallings-out have been reported to me, in each case a 2-year-old in isolation and therefore less constantly under nursing supervision. It is clear that less liberty than usual can be given to such patients, and no child under 3 years is now left alone and unprotected.

With few exceptions the nurses, including ward sisters, have come to look favourably on the new arrangement, which they regard as both time-saving and muscle-saving. The *Nursing Times* said recently: "With the shortage of labour so acute, it is important for all of us to economise in the expenditure of energy and time whenever we can."[1] This statement is endorsed by a publication of the Ministry of Aircraft Production on motion study,[2] the aim of which is to lighten the task of the industrial worker by doing away with waste of human effort. Nurses can well be drawn within the scope of this science, and this paper is in part an attempt to do so.

SUMMARY

The dropside cot for certain age-groups of children in hospital is condemned as unnecessary, noise-producing, not free from danger, and wasteful of nurses' time and energy.

I wish to thank the sisters and nurses of Shieldhall Hospital for their coöperation.

the familiar form with splenomegaly and the acute infantile form with the involvement of the central nervous system, there is a third type of Gaucher's disease without splenomegaly. This type may be relatively common, as its only symptoms are those of a mild anæmia. In such cases the diagnosis can only be made with certainty during life by finding Gaucher cells in the bone-marrow.

Cases of Gaucher's disease which are first diagnosed after the second or third decades are rare enough to arouse comment. Horsley et al. (1935) describe a case first detected at the age of 47. Mandelbaum et al. (1942) claim that their case is of interest because it was not recognised before the fifth decade. Wechsler and Gustafson (1940) describe a case in which the disease was first detected at the age of 68. Case 1 reported here was not detected until the age of 67. The family tree (fig. 4) shows that Gaucher's disease is suspected in some other members of the family who lived an active life until well over middle age.

There is considerable divergency of opinion about whether Gaucher's disease is congenital, familial, or hereditary. Pick (1933) states that it is congenital and familial, and that in about a third of the cases several members of one generation are affected, but that the disease is limited to that generation. Hoffman and Makler (1929) state: "in no series of children did either of the parents suffer from the disease, nor has it been transmitted from any adult to a child." Most workers seem to agree with these views but there are a few notable exceptions.

Bloem et al. (1936) report cases of Gaucher's disease in two families which had an apparently normal common grandfather. His son by his first wife had an enlarged liver; one of this son's seven children was a proved case of Gaucher's disease with splenomegaly, and two were suspect. By his second wife he had an apparently normal son; among the latter's nine children were one proved case and two suspected cases of Gaucher's disease. Anderson (1933) reports that an apparently normal male had nine children, four of whom had splenomegaly. Two of these were proved cases of Gaucher's disease, and the two other children were remarkable for their pallor. The paternal grandmother and her two sisters were said to have had large abdomens and brown skin and to have died from a similar illness.

Pachman (1938) refers to possible hereditary transmission but gives no pedigree.

Bychowski (1911) described a family in which a father and three children had splenic enlargement and probably had Gaucher's disease.

Plehn (1909) observed Gaucher's disease in a man and his daughter.

The present case 1 has been proved to have Gaucher's disease, and two of his three children provide radiological evidence of the disease. Other members of the family, from their histories and description, may well be affected but were not available for investigation.

It thus appears from the published records of previous cases that there are reasons for considering that Gaucher's disease may be hereditary, provided it is accepted that the condition may be transmitted by an apparently healthy person. The importance of the present series in this respect is that it reveals that Gaucher's disease is compatible with a long healthy life and can exist without those visceral enlargements which have previously been considered one of its invariable features. It is therefore possible that those apparently healthy subjects, who are suspected of having transmitted the disease, may in fact have been affected by the condition in the form here described.

SUMMARY

A family affected by Gaucher's disease, but in whom none of those affected show splenomegaly, is described. The diagnosis was made by the detection of Gaucher cells in the bone-marrow and by the presence of typical radiological lesions in the bones. The family suggests that in this series the disease was not congenital and familial but also hereditary. All
or were leading, active lives, and in one case the
was first made at the age of 67 years.

DISCUSSION

The possibility has not been overlooked that other members of the urinary steroid or 17-ketosteroid groups, particularly those most closely allied to dehydroisoandrosterone, may give similar colour reactions. Isoandrosterone gives the same reaction; it has been isolated from the urine in adrenal hyperplasia (Butler and Marrian 1938), but neither the amount isolated nor the results of the present work suggest that it would complicate the reaction in adrenal hyperplasia. Moreover there is no indication that it is present in urine from cases of adrenal tumour in amounts likely to contribute significantly to the chromogenic capacity of the adrenal-tumour extracts as prepared in this investigation.

Evidence has also been obtained that a third substance is present in urine from cases of adrenal tumour which can give a similar reaction. The nature of this substance has not yet been fully investigated, but it may prove to be $\Delta^{3:5}$-androstadiene-17-one, which was isolated from the urine of a male patient with a malignant tumour of the adrenal gland by Burrows et al. (1937), who showed that it could be prepared from dehydroisoandrosterone by dehydration. This same compound also appeared in appreciable quantity, though in considerably less amount than dehydroisoandrosterone, among the products isolated by Wolfe et al. (1941) from extracts of the urine of a female patient with an adrenal tumour. Since, however, it is only known to be present in urine from cases of adrenal tumour, it can only reinforce the dehydroisoandrosterone reaction when the latter is used in its present form for the purpose of indicating the presence of adrenal tumours.

SUMMARY

A new colour reaction for dehydroisoandrosterone here described will demonstrate the presence of excess of this compound in extracts of urine from cases of adrenal tumour.

Under comparable conditions urines from cases of adrenal hyperplasia give negative results; hence the reaction differentiates cases of adrenal tumour from other adrenal cases with high 17-ketosteroid output.

The same reaction is given by isoandrosterone, and by a third substance present along with dehydroisoandrosterone in urine from cases of adrenal tumour. Neither of these additional compounds complicates the reaction in the diagnosis of adrenal tumours.

I am particularly indebted to Mr. L. R. Broster, whose cases have furnished the greater part of the clinical material in this investigation, and to Dr. C. W. Shoppee for a sample of pure isoandrosterone.

Medical Societies

ROYAL SOCIETY OF MEDICINE

Poliomyelitis and Meningo-encephalitis

AT a meeting of the section of epidemiology and State medicine on Oct. 6, with Dr. W. S. C. COPEMAN in the chair, Mr. K. I. NISSEN described the outbreak of poliomyelitis on the island of St. Helena in 1945–46.

There were 216 cases with 11 deaths, the attack-rate being 5% of the population. The outbreak began in November, 1945, and was over by the end of the following January. None of the patients was under one year of age and only 5 were under five years. Most of the cases were in the 5–20 years age-group and most of the deaths in the 15–20 group. There were no cases among the small garrison of European troops. The last ship to call at the island before the outbreak did so thirty-one days before the onset of the first case; this patient was the fiancée of a soldier travelling on the ship and had been visited by him for a few hours on the day the ship called. A few British troops were embarked during the call at St. Helena and among them was a sergeant who reached his home at Ealing fifteen days later. The daughter of this sergeant, aged four years, developed poliomyelitis eleven days after his arrival home. No other cases were reported as travelling in or otherwise connected with this ship, which came from South Africa and called at St. Helena when less than a week out from Capetown. Food and water supplies were not thought to be connected with the spread of the outbreak. Transmission of infection to outlying districts appeared to be by human carriers, often apparently healthy and usually adults. Clinically just over 60% of the cases were non-paralytic and might be regarded as “ abortive.” A characteristic early sign appeared to be a cold bluish-grey appearance of the tongue. There was also a characteristic odour of the fæces which persisted several days after the fall in temperature.

Dr. ALLAN MCFARLAN commented on the long interval between the arrival at the island of the ship which was the suspected source of infection and the onset of the first paralytic case. He did not think that this case was an instance of a direct infection with a long incubation period, but realised the difficulties in such urgent circumstances of making an adequate retrospective investigation into the possibility of a chain of infections linking the source with the first recognised case.

Dr. L. J. M. LAURENT gave an account of a series of 13 patients apparently suffering from a form of meningo-encephalitis of unknown ætiology who were admitted to the Park Hospital, London, during the summer months of 1946. None of these patients showed any evidence of spinal paralysis and all but one recovered. A careful pathological investigation had been made of the fatal case. An infiltration of the meninges with large mononuclear cells was the outstanding histological feature. In the pons, midbrain, and the region of the basal ganglia there were small areas of perivascular cuffing with the same type of cells. No neuronic degeneration could be found in the medulla or spinal cord, and attempts to isolate a virus by inoculating animals with serum, cerebrospinal fluid, and parts of the central nervous system had been unsuccessful. It was not considered likely that these patients had a form of poliomyelitis, but Jennings [1] had reported a similar series which occurred at about the same time of year in an area affected by an outbreak of poliomyelitis. Careful investigation had failed to disclose any connexion between the Park Hospital patients and known cases of poliomyelitis. In only one of the patients was it probable that other persons in the same household had a similar illness. During the summer of 1947, when poliomyelitis had been prevalent in London, 2 further cases clinically resembling the 13 observed in 1946 had been admitted to the Park Hospital.

Dr. DOUGLAS MCALPINE said that the current epidemic of poliomyelitis differed from previous English experience of the disease in clinical features as well as in extent. He was inclined to postulate the recent introduction of a new strain of virus and made a plea for the provision

Preliminary Communication

DIAGNOSIS OF ADRENAL TUMOURS

A NEW CHEMICAL TEST

INVALUABLE as the estimation of urinary neutral 17-ketosteroids has proved in the diagnosis of adrenal tumours, in which cases extremely high values are often encountered, the method is incapable in many instances of differentiating between adrenal tumour and adrenal hyperplasia. Especially does the group classified as prepubertal virilism (Broster et al. 1938) yield very high figures, with the result that on the scale of daily output of 17-ketosteroids there is a considerable overlap between tumour and non-tumour cases (Patterson et al. 1942, Callow and Crooke 1944). It is therefore evident that, where the problem of differential diagnosis arises, further laboratory investigation may be required, and the manner in which this may be most usefully carried out has engaged the attention of many workers in recent years.

Most research has been centred on one of the members of the 17-ketosteroid group, dehydroisoandrosterone, which was first demonstrated by Callow (1936) in relatively large amounts in urine from a case of adrenal tumour. It was isolated from an extract of the urine by the formation of its sparingly soluble benzoate. Crooke and Callow (1939), using the same procedure, found in two tumour cases that the increase in 17-ketosteroid output was largely due to an increase in the output of this substance. Subsequently Talbot et al. (1940) used the differential estimation of the separated α and β ketosteroid fractions to reveal the presence of dehydroisoandrosterone by a well-marked increase in the ratio of β to α compounds; and Callow and Crooke (1944) applied the original benzoylation technique and a modification which involved prior separation of the β fraction to the investigation of adrenal cases. The application of these principles, together with some notable work on the fuller fractionation of the 17-ketosteroids (Wolfe et al. 1941, Mason and Kepler 1945), has amply confirmed that the presence of relatively large quantities of urinary dehydroisoandrosterone constitutes a distinguishing feature of adrenocortical tumours in female subjects.

During experiments on the possible chromogenic properties of dehydroisoandrosterone it was found that the pure crystalline substance gave an intensely violet-blue colour with some green fluorescence when treated with sulphuric acid in the sequence of steps described below. The reaction was capable of being made sensitive down to less than 0·1 mg. Subsequently it was ascertained that this reaction could be used to detect excess of the compound in extracts prepared for the ordinary 17-ketosteroid assay of urine from cases of adrenal tumour and, for diagnostic purposes, could be substituted for the much more complicated and time-consuming methods hitherto used.

METHOD

Collection of Urine.—A 24-hour specimen is collected into a Winchester quart bottle, containing either 5 ml. of chloroform or of toluene, or 10 ml. of 30% sulphuric acid as preservative, and is used as soon as possible after the collection is complete.

Preparation of Extract.—25 ml. of urine is hydrolysed by adding 0·75 ml. of concentrated sulphuric acid and heating to boiling under a reflux condenser for 30 min. After cooling, the urine is extracted in a separating-funnel with two lots of peroxide-free ether, 30–35 ml. of solvent being used each time. The combined ether extracts are washed with 5 ml. of 10% sodium hydroxide and then with 5 ml. of the same alkali in which is dissolved a knife-point of sodium hydrosulphite. The period of vigorous shaking with the latter should not be less than 2 min. After the alkali has been off, the ether extract is washed with three 5-ml. lots of water. The washed extract is quantitatively transferred the aid of a little more ether into a 100-ml. flask, about 0·1 of 'Norit' (or other suitable decolorising charcoal*) is and the ether is evaporated down to a volume of 8–10 ml. It is then filtered through a small cotton-wool fitted fairly tightly into a small glass funnel so as to be cap of retaining every trace of charcoal. The flask and the are washed with two further lots of 5 ml. of ether, and whole of the filtrate is taken down to dryness, the ext being then dissolved in 1 ml. of absolute alcohol; 0·2 ml. this solution is used for the preliminary estimation of 17- steroids in the usual way (for detailed technique see C et al. 1938). According to the intensity of the colour the residual alcoholic solution is later used in dilution with alcohol for a second and more accurate while the rest is taken for the dehydroisoandrosterone reaction.

Dehydroisoandrosterone Colour Reaction.—0·2 ml. of alcoholic solution is transferred to a dry test-tube evaporated to complete dryness in a vacuum 1 ml. of concentrated sulphuric acid is added, and the shaken until the extract is completely dissolved. It is kept in a water-bath maintained at a temperature of for 20 min. The tube is next immersed in cold water, and 1 of distilled water is added drop by drop down the side wi shaking. The diluted solution is then heated in a boi water-bath for 1 min., during which time the blue colour develops if the dehydroisoandrosterone is present in signific amounts. Heating for several minutes in the last stage d not appreciably alter the colour, which is very stable. Extra from urine which does not come from a case of adrenal tum give various shades of brown.

RESULTS

The test has been applied to three cases of adre tumour, all in females. On the day that the urine w collected for the tests they had 17-ketosteroid outputs 215 mg.,† 335 mg., and 1980 mg.‡ All gave inte reactions.

In contrast to these results are the series of complete negative results obtained from six cases of prepubertal virilism which had 17-ketosteroid outputs ranging fro 24 to 81 mg. a day. Whereas in the tumour cases the fin extract could be diluted until the amount of tota 17-ketosteroid was no more than 0·2 mg. in the sampl under test and still gave an appreciable colour, in th other group no reaction was seen at levels of 1 mg. o more of total 17-ketosteroid. Some experiments based on the addition of known amounts of pure dehydroisoandrosterone to extracts of urine from cases of prepubertal virilism showed that the reaction could be masked by the presence of a high proportion of the other constituents in the extract. A negative reaction therefore does not necessarily mean the absence of dehydroisoandrosterone, but only that it is not present as a major constituent.

Application of the reaction to eight cases of second virilism, selected because they had 17-ketosteroid tions in the higher part of the range for this group, i.e., from 21 to 30 mg. a day—has given uniformly negative results.

With the clinical material available it has so far only been possible to apply the test to tumour cases in which the ketosteroid output was so high that a definite diagnosis on that ground alone could be established with certainty. It is therefore impossible to dogmatise on its full potentialities, but in view of its demonstrably high sensitivity there seems to be no fundamental reason why it should not apply over a much wider range and to more difficult cases.

---

* For accurate estimation of ketosteroids, but not necessarily for the qualitative dehydroisoandrosterone reaction, the charcoal should be previously tested and only used if it does not remove any 17-ketosteroids from ethereal solution.

† Case previously described (Anderson et al. 1943).

‡ Case awaiting publication (Broster).

introducing DERMUCID

British Schering have pleasure in presenting a new dermatological cream containing 8% 'Albucid' (sulphacetamide) in a vanishing cream base.

Rapidity of absorption facilitates the penetration into the skin of the active principle 'Albucid', thus enabling an effective bacteriostatic action to be exerted at the site of infection with a minimum of cosmetic embarrassment.

'Dermucid' is especially suitable for application to exposed areas of the skin and is recommended for the treatment of impetigo, sycosis barbae and secondarily infected lesions.

THIS IS A BRITISH SCHERING PRODUCT

BRITISH SCHERING LIMITED

TRAUMATIC SHIN ULCER

HEALED WITH JELONET, VISCOPASTE, PARAGON SPONGE RUBBER & ELASTOPLAST

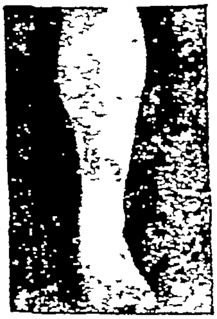

Fig. 1

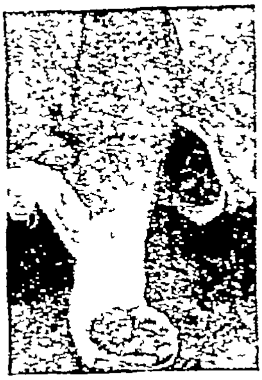

Fig. 2

Case History

G.H.H. Aged 38. Dock Labourer. Injured his left shin whilst at work. On attending the clinic he had a deep traumatic ulcer surrounded by an inflamed area of skin . . . no varicose veins. (Fig. 1.)

Treatment. *August 9th*, 1946.—Jelonet was applied to cover the ulcer and inflamed area, and a pad of cotton-wool to cover the ulcer only. The leg was bandaged from toes to knee with Viscopaste. (Fig. 2.)

August 23rd, 1946.—The inflamed area was re-dressed with Jelonet covered by strips of Ichthopaste. A well bevelled adhesive sponge rubber pad was applied to cover the ulcer, and the leg firmly bandaged with Elastoplast.

Sept. 13th, 1946.—After liberally painting with calamine in oil, covered with Ichthopaste, a large pad of cotton-wool was placed to cover the ulcer and the leg again firmly bandaged with Elastoplast.

October 4th, 1946.—Ulcer healed. (Fig. 3.)

October 18th, 1946.—Patient discharged to work.

Comment. Although initial bandaging with Viscopaste resulted in marked improvement, there was not sufficient pressure as was evident on August 23rd when, although the ulcer was reduced in size, there was pronounced granulation tissue. This resolved rapidly with concentrated compression beneath sponge rubber with the additional support of Elastoplast. (August 23rd and September 13th.)

Details and illustrations above are of an actual case, T. J. Smith & Nephew, Ltd., Manufacturers of Jelonet, Viscopaste, Ichthopaste and Elastoplast are privileged to publish this instance, typical of many, in which their products have been used with success, in the belief that such authentic records will be of general interest.

and training of more laboratory and field workers to investigate unusual outbreaks of virus diseases at short notice.—Dr. F. O. MacCallum spoke on the difficulties likely to be encountered in organising work of this kind.

Reviews of Books

Current Therapies of Personality Disorders

Editor: Bernard Glueck, M.D. London: W. Heinemann. 1946. Pp. 296. 17s. 6d.

How is the busy practitioner to learn which of the many books and papers coming his way deserve his time and study? The answer seems to be, by bush-telephone —by someone handing on his personal judgment of what someone else has handed on to him. There are many to whom this book should be handed on. Somehow, nineteen papers given at the thirty-fourth annual meeting of the American Psychopathological Association and reprinted here have achieved a unity. Nineteen skilled, educated, and thoughtful therapists have cogitated on their subject; none of them suggests finality, none has found "The Way"; but though they are walking along separate roads they are going in one direction—towards the freeing of the mind.

On the wide frontier of psychiatric practice small irregularities do not show; but Dr. Robert M. Lindner makes a significant outward dent with his evaluation of hypno-analysis. Both his theory and his warning of danger demand and easily receive a second reading. Group therapy is assessed by several practitioners, drug treatment is fully reported, and family guidance receives its measure of advocacy and explanation. The use to which psychiatry was put in war selection of personnel, with its ruthless emphasis on function—how useful the sailor or soldier would be to the organisation—reads strangely among a group of papers which stress the opposite value —the Socratic ideal of the physician. The book, packed with concrete evidence, will appeal to all those who have some knowledge of and some interest in psychotherapy and who wish to know where we have got to.

Annual Review of Biochemistry

Vol. xv. Editors: J. Murray Luck; James H. C. Smith; Hubert S. Loring; Stanford University. London: H. K. Lewis. 1946. Pp. 687. 30s.

In the sciences allied to medicine, dozens of discoveries are made each year of a quality which would have aroused the widest interest and excitement a decade or so ago, but they now raise little comment. We are not over-sophisticated; we are overwhelmed. The biochemist is particularly unfortunate since his interests cover such a wide field, and he has to rely on the *Annual Review* and the subject indexes of the abstract journals to give him the key to the previous year's publications. It is announced that an *Annual Review of Microbiology* will begin to appear in 1947. If more and more of the applied aspects of biochemistry could thus be shed until a parent volume is left containing only work on fundamental principles, most readers would value it still more. In the present volume the fundamental aspects are given their full due, however, and special subjects reviewed include the biochemistry of teeth, the growth factors for micro-organisms, immunochemistry, the viruses, and the inactivation and detoxication of pressor amines.

Care of the Breast

Else K. La Roe, M.D. New York: Froben Press. 1947. Pp. 246. $3.75.

The publishers of this work hope that it will make women "breast-conscious," and persuade them "that a competent doctor should be consulted at the first sign of any change or peculiarity." It covers the anatomy, physiology, endocrinology, and morbid anatomy of the breast. Malignant new-growth and surgery, including plastic surgery, are particularly considered, and "a new concept is propounded regarding the causation of cancer, based on the significance of growth hormones and their anarchic potentialities under specific conditions." The book is lucidly written and superbly illustrated, but it is rather too ambitious in its aims. To the lay reader the discussion of "all possible diseases, injuries, and inflammations" and of "the latest methods of breast examination" will be confusing and apt create breast-conscious hypochondriacs. The of surgical procedures may appeal to surgeons experienced in this special branch, since it will them to compare ideas and methods on the two sides of Atlantic, but details of operations do not mean m to the general practitioner and are frightening to average woman. As a comprehensive and well-produc account of one organ, however, the book will have uses.

Human Torulosis

A Clinical, Pathological and Microbiological Study *a report of thirteen cases.* Leonard B. Cox, F.R.A.C.P., neurologist, Alfred Hospital, Melbourne; J C. Tolhurst, M.Sc., senior bacteriologist to the hosp London: Oxford University Press. 1946. Pp. 149.

Only 120 cases of human torulosis have been rec nised and recorded. Most of the patients have b Australians, though occasional cases have occurred other places, including England. Torulosis is a chro disease which sometimes appears alone, but often conjunction with other diseases; it is found most of in the central nervous system. Clinically it is not e to distinguish, from tuberculosis, and sometimes fro syphilis; but its pathology and bacteriology are evident fairly distinctive, as the authors show. Iodides an sulphonamides have been tried, and sulphadiazin brought about slight temporary improvement. Penicilli and streptomycin are not mentioned, but X rays hav been used. This is a good book on a rare but highly fata condition.

Dolores Mortales

M. L. Esnaurrizar, surgeon to the Clinica Fr of the Mexican Academy of Surgery. Mexico. 19 Pp. 67. $15.

Pain serves a useful purpose in making the patient se medical advice, but colic can kill because of the intensit of the pain, or as the result of morphine or barbiturat given to relieve it. That the sympathetic chain is th main means of transmitting the dread and sometim fatal pain of organic lesions is suggested here and ther in medical literature, and this led Dr. Esnaurrizar to a study of the "physiopathology" of the sympatheti chain. On the clinical side this consisted in injecting local anæsthetic into the nerve, and, when relief of pain confirmed that the point of the needle was correctly lodged, injecting alcohol, which gave freedom of pain for 15–40 days. In appropriate cases he has seen much improvement from an injection of 8–15 cm. of 96% ethyl alcohol. The amount seems large, but he is definite that he has seen no trouble of any significance as a result. His technique is beautifully illustrated by drawings.

Clinical Examination of the Nervous System (8th ed. London: H. K. Lewis. 1947. Pp. 380. 16s.).—The basic clinical methods of examination of the nervous system do not change much, so in essence Prof. G. H. Monrad-Krohn's handbook is much the same as it was before the war. The notable extensions of neurological methods of examination in recent years have been in radiology and electrophysiology; and this edition contains 30 pages on the radiology of the skull and brain, with numerous plates of encephalograms and arteriograms made in Professor Monrad-Krohn's clinic—which has done advanced work in this field. Later editions will no doubt deal with electro-encephalography as adequately.

Recent Advances in Medicine (12th ed. London: J. & A. Churchill. 1947. Pp. 442. 21s.).—Dr. G. E. Beaumont and Prof. E. C. Dodds, in their latest edition, have revised this book thoroughly and added about 100 pages. So as not to add to its bulk they have omitted the sections dealing with the kidneys and with diphtheria. Sections on the sulphonamides and synthetic antimalarial drugs have been brought up to date, and the new penicillin chapter carries accounts of other antibiotics as well. The latest ramifications of the vitamins are given their due, and there are new articles on thiouracil, primary atypical pneumonia, infective hepatitis, homologous serum jaundice, bone-marrow transfusion, and the use of thiocyanates in the treatment of hypertension. New prospects in œstrogen therapy fill an inviting section of the chapter on sex hormones.

THE LANCET

LONDON: SATURDAY, OCT. 18, 1947

The Barbiturates

s 1934 a short-lived but violent controversy[1] d round the risk of poisoning by barbiturates. haps the attack on them was too intemperate; ainly the defence seems to have been successful, whereas in 1934 orders for this group of drugs prised 1·1% of all National Health Insurance scriptions, they now account for 4·6%: and if comparison is based on cost of ingredients of scriptions, the barbiturates' share of the total risen from 1·5% to 5·4%.

he increase is to some extent explained by the ing vogue of bromides. Bromides certainly had their wbacks: sometimes they depressed the patient rought him out in spots, and they were sometimes ifiably indicted as a cause of delirium. The biturates have largely been used in the treatment epilepsy; and their use has been extended to other ditions, such as hyperpiesia and migraine, where ir application if not always rational is usually ensible. Practitioners have also come to rely on m in the treatment of minor psychiatric disorders l sleeplessness, and for the palliation of many disers where the diagnosis is uncertain or where no rnative treatment presents itself. These drugs thus achieving the same status with the doctor t aspirin has long held with the layman. Some chiatrists would ascribe much of their increased to the more frequent diagnosis of psychiatric abilities.

here is no doubt, of course, that these drugs are y valuable, provided they are used with proper crimination. Some of the group—for example, dium amytal' and phenobarbitone—have been wing in favour, while others such as barbitone are comparatively seldom prescribed. Fashion and nouncements in textbooks have no doubt played ir part, but there are rational indications for choice of a particular drug, depending on its mptness of action and duration of effect. These perties largely depend on the saturation of the yl side-chain, the unsaturated members of the up having a shorter effect because of their quicker struction in the body. Thus phenobarbitone, which eliminated mainly through the kidneys, acts preciably longer than sodium amytal or pentorbitone, both of which are broken down in the liver. e rate of excretion or destruction will obviously influenced by renal or hepatic disease which makes the use of an otherwise safe dose risky and its frequent repetition dangerous. Dosage must always be determined in the light of the normal pharmacological action, of the ratio between therapeutic and lethal dose, and also of the responsiveness of the subject: the patient who is comfortable and tranquil needs less than the one who is in discomfort or distress; and the more irritable the patient's nervous system the larger the dose necessary to exert an effect. Through lack of supervision or a too ready attribution of symptoms to a functional origin, patients taking barbiturates are sometimes allowed to spend the first half of each day in a cloud of weariness and lassitude whose true origin remains unrecognised.

To prevent their uncontrolled use by the public the law has placed the barbiturates among the first-schedule poisons, issued only against a prescription. This very safeguard, however, fosters another danger. The doctor ordering one of these drugs for sustained use is likely to prescribe a large number of tablets at a time, so that the patient need not return soon merely for a further prescription; and such generous supplies may tempt some patients to excessive dosage, besides constituting a danger to children. Accordingly some practitioners, with commendable caution, make it a rule never to prescribe at one time enough barbiturate tablets to be lethal if taken in a single dose; and this should be the ideal, if only because small prescriptions bring the patient back more often for supervision. Fortunately, there is little risk of addiction, though Hambourger[2] has shown that habituation and undue dependence can occur. But the risk of accidental or suicidal poisoning is by no means negligible. In Hambourger's series acute poisoning accounted for 0·05% of all admissions to thirteen large American hospitals; and Goldstein[3] has since reported a growing number of deaths and non-fatal cases from this cause. In the States of California, Illinois, Massachusetts, and Ohio there were 367 deaths from this cause in 1945, compared with 104 in 1936. Unfortunately no comparable figures have been published in this country.

Clearly barbiturates are not the harmless sedatives that their present wholesale distribution might suggest.[4 5] Constant watch must be kept for chronic intoxication: impaired concentration, drowsiness, vertigo and ataxia, thick speech, nystagmus, difficulties of accommodation, and paresis or tremor are among the possible manifestations. It is even more important to bear in mind the possibility of acute intoxication, which demands prompt and energetic treatment. Patients unable to sleep but fuddled by a previous dose of barbiturate of which they remember nothing have been known to poison themselves accidentally by reaching for further tablets; and this has prompted some physicians to place the drug in the keeping of some other member of the household. Whatever expedients and safeguards may be adopted, it is clear that the many advocates of the barbiturates should at all times bear in mind the perils as well as the blessings of the drugs they prescribe.

MYCIL

A new fungicidal preparation

A fungicidal substance of a new type has been evolved in the Research Laboratories of The British Drug Houses Ltd.—*p*-chlorophenyl-α-glycerol ether. Under the name Mycil, preparations of this substance are now available for the treatment of athlete's foot and associated conditions such as hyperhidrosis and the resulting soreness and tenderness.

p-Chlorophenyl-α-glycerol ether is an active fungicidal and bactericidal substance of which Mycil Ointment contains 0.5 per cent. and Mycil Dusting Powder 1 per cent.

Ointment and Dusting Powder are used collaterally so as to provide intensive medication and to reduce the possibility of reinfection.

ining centres, supported by special tests and by ychiatrists' reports, are, as never before, helping fit square pegs into square holes. Thirdly, the dier must be protected from illness by public-health asures such as immunisation and the surveillance water-supplies. Finally, the soldier's environment ist be watched, and if necessary modified; and it a greater interest in environment at close quarters t Dr. **Gear** particularly urges in his article else- ere in this issue. Like H. L. **Marriott** before him, AR pleads for a change of emphasis in our military dical services. As consulting physician to the AC land forces **Marriott** wrote[1]: "At least four- hs of our sickness casualties have been due to ease capable of classification as 'preventable'"; m which he concluded[2] that more men should be otted to the hygiene service and that regimental dical officers should be given encouragement and thority to tackle preventable illness. The R.M.O. n a better position than anyone else to teach giene to his unit and to foster their health and ll-being; and he alone can detect and remove the st roots of disease before the start of that insidious ckle of sick to the rear which saps the strength and rale both of those who go and of those who stay.

The efficiency of the curative services in the late r has been rightly commended; but before the ons of war are relegated to the history-books we ask whether a more aggressive policy of preven- might not have substantially reduced the calls on se services. Many who served as R.M.O.'s received tle incentive to pursue such a policy. Denied any ospect of promotion while continuing in their esent employment, cut off from the stimulating ntact with other doctors and with the more seriously patients, and sometimes accorded scant encourage- ent by the unit's commanding officer, some threw their hands and did little more than regulations emanded. In such circumstances a man, particu- rly if young and lacking a forceful personality, cannot greatly blamed if he does "just sit around feeling orry for himself that he is not doing something hich he thinks more important—i.e., working in ospital."[3] If the R.M.O. is to accept wider responsi- ities he must be encouraged; he must be made to el—what indeed should be the truth—that he and hose like him are the bedrock on which the medical ervices are built. If the work of prevention is to be one properly, medical officers must be given more nstruction in the broad principles, both as students nd on entry to the Army; and they must be offered ewards for good and responsible service in the rospect of promotion to field rank, those who fail eing withdrawn to medical units where they will be upervised by senior medical officers. But that is ot all: if the R.M.O., who now often feels that he is orking in a vacuum, is to retain his enthusiasm for duties which are largely arbitrary and voluntary, he must be constantly inspired by the direction and advice of a wise administrator. In his A.D.M.S. he should find support informed by personal knowledge. Lieut.-General Sir **Alexander Hood**, director-general of Army Medical Services, has postulated that the administrator should be "not the specialist in adminis- tration, but the doctor who has worked his way through many and various departments and specialties before starting to administer."[4] So far no attempt has been made to sponsor regular meetings of R.M.O.'s on the scale of those held successfully in Army hospitals; yet such meetings would give the R.M.O. a chance to judge his results against other peoples'. (Why is there so much grousing about food in unit A, while in unit B, with comparable cooking, complaints are rare? Why does the sick-parade in infantry battalion C number only 11 per day, while in battalion D, just down the road, the daily rate is 23? How comes it that in unit E 4 patients, previously well, have mild anxiety states?) Finally, if field research into preventive methods is to be given the weight it merits, further senior specialists should be appointed, whose main task would be to tour units, helping medical officers with local problems and guiding them in the conduct of on-the-spot research.

Books from Abroad

Most of us have been brought up to believe that progress largely depends on the free circulation of thought. Since the end of the war politicians of some nations have slowed, and at points stopped, this free circulation; and we have damned them for it. Now the clamp is to be gently applied to Britain—not, it is true, from political motives but from economic need. On another page Dr. **Israëls** protests at the ban on the import, except under licence, of books from abroad; and his remarks will strike a chord in all who recognise the necessity for the flow of knowledge between the countries. The position now is that "learned, scientific, and technical books in English" may be imported from abroad by booksellers up to, but not beyond, the value of their pre-war purchases; which, since prices have risen, means that only about two-thirds of the number of books imported in 1939 will reach the country in this way. Applications for licences to import books in foreign languages, and applications from firms with no pre-war imports, will be considered "on their merits"; while private persons wanting particular books may apply through their bank for permission to buy them abroad. This ruling will presumably cause foreign books to disappear from the bookshops, for booksellers are likely to use up their quota on specific orders from their customers. If no difficulty is placed in the way of individual purchase of single copies, the purchaser may suffer no more than inconvenience; but if, on the other hand, this part of the regulation is grudgingly interpreted, it will insidiously but progressively reduce our intellectual and technical contacts with other lands, particularly with America. Impediments of this kind became familiar during the war, and were generally tolerated; but at a time when so much hangs on our not falling behind, in science or in industry, they cannot be accepted without question. A wide choice of imported books is certainly more valuable to this country than tobacco, and as "essential raw materials" books can even compete with food. We must face the fact that what we cannot pay for, we cannot have. At the same time this new regulation is one of the most disquieting so far produced by the economic crisis, and its effects will be anxiously watched; for it contains a precedent alien to a free people.

Rocky Mountain Spotted Fever

IN parts of America and Africa a closely related group of tick-borne rickettsial infections are endemic, and one of these is Rocky Mountain spotted fever, which RICKETTS,[1] in 1907, showed to be caused by an agent now known as *Rickettsia* or *Dermocentroxenus ricketti*. At that time the disease was thought to be confined to the western part of the United States, but later a much wider distribution was recognised. As early as 1912 cases of a similar disorder were seen on Long Island, New York State; but it was not until 1931 that DYER et al.[2] isolated the rickettsia of eastern Rocky Mountain spotted fever and found that it was antigenically similar to the agent of the western form.

Some idea of the importance of this disease can be obtained from the report of a recent symposium held in New York.[3] The epidemiology of the infection is closely associated with the biology of the tick.[4] The vector in the west is the wood-tick, *Dermacentor andersoni*, and in the east the dog-tick, *Dermacentor variabilis*; several other ticks, such as *Amblyomma americanum* on the Gulf coast, may also act as vectors. The tick has a complicated life-cycle, passing through the four stages of egg, larva, nymph, and adult. An infected female can transmit rickettsias to her eggs and throughout all stages to successive generations; thus the tick serves not only as a vector but as a reservoir for rickettsias. The disease is commonest in the summer, when ticks are abundant. Several small rodents act as host during the developmental stage, but the dog is the important host for the adult tick. Ingestion of mammalian blood by the adult tick results in a multiplication of the rickettsias and an increase in their pathogenicity—so-called "reactivation." The exact rôle of the dog is not certain; it undoubtedly acts as host to the tick and itself becomes infected, as is shown by the high complement-fixation titre of the serum of dogs in infected localities. How the disease is transmitted to man has yet to be decided; but it is significant that many cases are seen without any evidence of a tick bite or local lesion. Rickettsias present in tick fæces, reactivated by ingestion of blood, may penetrate the skin or be inhaled as fine particles. This certainly happens in other rickettsial infections such as epidemic and scrub typhus and may well be the means of infection in Q fever. Thus there seems to be a definite risk in handling dogs harbouring infected ticks. The apparent differences in severity between the eastern and western forms are probably due to minor differences in rickettsial strains, such as occur in any infectious disease, and to the fact that in the west a different population is at risk. There the disease is found most often in old people, so the mortality-rate is higher than in the east where over half the cases are in children under the age of 12 years.

Nearly 100 cases of eastern spotted fever have been recorded in New York State since 1912, most of them in Suffolk county at the eastern end of Long Island. The symptoms are remarkably uniform and similar to those seen in other rickettsial tions. The onset is sudden with chills, fever, muscle pains accompanied by profound with every indication of involvement of the system. The temperature tends to remain 103–105°F—falling by lysis in the third week; pulse-rate is not greatly raised. A rash was present in all the New York cases; it appeared about the third day as a macular on the extremities, particularly on the palms soles; but it later became petechial and spread the trunk. Tick bites were seen in only 10% cases, and splenomegaly in only 20%. The Felix test is of some value in diagnosis. agglutinins to *Proteus OX19*, as with epidemic murine typhus, begin to appear on or about eleventh day, the titre rising during c Recently more specific results have been with complement-fixation tests employing rickettsial suspensions as antigen. The lesion is an acute infection of the small blood-throughout the body, particularly in the skin brain, which leads to thrombosis and later to and hæmorrhages. The basis of all treatment therefore rest in the acute and convalescent Specific immune antiserum has provided good when given early in the disease,[4] and so has p benzoic acid, which reduces the toxic mani *Two vaccines are used in prophylaxis*, one from infected ticks and the other from the of the developing chick-embryo, as described Cox.[6] Both have given encouraging results.

Meanwhile, eastern spotted fever, with a *fatality rate of 30%*, must be attacked by the public in its cause and method of spread, prophylactic vaccination, and by attempts to the tick population.[7]

A Change of Emphasis

THE opportunity for promoting "positive is nowhere greater than in the Armed Forces; here, as in no other walk of life, groups of fit men are brought together in an environment they may be ordered, instructed, or guided in the they live. In time of war the opportunity is by the need; then men are scarce and trained still scarcer; and during a campaign every man ill is not only a negative loss but a positive drag the whole force, for he must be evacuated, hospital treatment, and replaced by another Thus the first duty of a military medical service to keep men fit and in the field; and every case preventable illness is a defeat for that service.

On what does the avoidance of disease de In the first place, the soldier must be physically for the duties he is called on to undertake. In week's Chadwick lecture, summarised on another Brigadier RICHMOND referred to the Army's systems of medical categorisation and physical ing, which together go far to assure that no shall break down through physical in Secondly, men must be given work suited to aptitude and experience; in this respect the ining centres, supported by special tests and by chiatrists' reports, are, as never before, helping fit square pegs into square holes. Thirdly, the lier must be protected from illness by public-health sures such as immunisation and the surveillance water-supplies. Finally, the soldier's environment st be watched, and if necessary modified; and it greater interest in environment at close quarters t Dr. GEAR particularly urges in his article else-re in this issue. Like H. L. MARRIOTT before him, AR pleads for a change of emphasis in our military dical services. As consulting physician to the lc land forces MARRIOTT wrote[1]: "At least four-hs of our sickness casualties have been due to ase capable of classification as 'preventable'"; n which he concluded[2] that more men should be tted to the hygiene service and that regimental dical officers should be given encouragement and hority to tackle preventable illness. The R.M.O. in a better position than anyone else to teach iene to his unit and to foster their health and ll-being; and he alone can detect and remove the t roots of disease before the start of that insidious kle of sick to the rear which saps the strength and rale both of those who go and of those who stay.

The efficiency of the curative services in the late r has been rightly commended; but before the ons of war are relegated to the history-books we ask whether a more aggressive policy of preven- might not have substantially reduced the calls on e services. Many who served as R.M.O.'s received tle incentive to pursue such a policy. Denied any spect of promotion while continuing in their sent employment, cut off from the stimulating ntact with other doctors and with the more seriously patients, and sometimes accorded scant encourage-nt by the unit's commanding officer, some threw their hands and did little more than regulations manded. In such circumstances a man, particu-rly if young and lacking a forceful personality, cannot greatly blamed if he does "just sit around feeling ry for himself that he is not doing something hich he thinks more important—i.e., working in spital."[3] If the R.M.O. is to accept wider responsi-ties he must be encouraged; he must be made to el—what indeed should be the truth—that he and ose like him are the bedrock on which the medical vices are built. If the work of prevention is to be ne properly, medical officers must be given more struction in the broad principles, both as students d on entry to the Army; and they must be offered wards for good and responsible service in the spect of promotion to field rank, those who fail eing withdrawn to medical units where they will be pervised by senior medical officers. But that is ot all: if the R.M.O., who now often feels that he is orking in a vacuum, is to retain his enthusiasm for uties which are largely arbitrary and voluntary, he ust be constantly inspired by the direction and dvice of a wise administrator. In his A.D.M.S. he hould find support informed by personal knowledge. ent.-General Sir ALEXANDER HOOD, director-general f Army Medical Services, has postulated that the dministrator should be "not the specialist in adminis-ration, but the doctor who has worked his way through many and various departments and speciali before starting to administer."[4] So far no atten has been made to sponsor regular meetings R.M.O.'s on the scale of those held successfully Army hospitals; yet such meetings would give R.M.O. a chance to judge his results against ot peoples'. (Why is there so much grousing about f in unit A. while in unit B, with comparable cooki complaints are rare? Why does the sick-parade infantry battalion C number only 11 per day, wh in battalion D, just down the road, the daily r is 23? How comes it that in unit E 4 patie previously well, have mild anxiety states?) Fina if field research into preventive methods is to given the weight it merits, further senior speciali should be appointed, whose main task would be tour units, helping medical officers with local proble and guiding them in the conduct of on-the-s research.

Books from Abroad

MOST of us have been brought up to believe t progress largely depends on the free circulation thought. Since the end of the war politicians of so nations have slowed, and at points stopped, this f circulation; and we have damned them for it. N the clamp is to be gently applied to Britain—not, i true, from political motives but from economic ne On another page Dr. ISRAËLS protests at the ban the import, except under licence, of books from abroa and his remarks will strike a chord in all who recogn the necessity for the flow of knowledge between countries. The position now is that "learned, sci tific, and technical books in English" may be impor from abroad by booksellers up to, but not beyond, value of their pre-war purchases; which, since pri have risen, means that only about two-thirds of number of books imported in 1939 will reach country in this way. Applications for licences import books in foreign languages, and applicati from firms with no pre-war imports, will be conside "on their merits"; while private persons wanti particular books may apply through their bank permission to buy them abroad. This ruling presumably cause foreign books to disappear from bookshops, for booksellers are likely to use up th quota on specific orders from their customers. If difficulty is placed in the way of individual purch of single copies, the purchaser may suffer no more th inconvenience; but if, on the other hand, this part the regulation is grudgingly interpreted, it will insi ously but progressively reduce our intellectual a technical contacts with other lands, particularly wi America. Impediments of this kind became famil during the war, and were generally tolerated; but a time when so much hangs on our not falling behi in science or in industry, they cannot be accept without question. A wide choice of imported books certainly more valuable to this country than tobac and as "essential raw materials" books can even co pete with food. We must face the fact that what cannot pay for, we cannot have. At the same ti this new regulation is one of the most disquieting far produced by the economic crisis, and its effects be anxiously watched; for it contains a precede alien to a free people.

TRAINING THE SPECIALIST

FEW are content with present arrangements for the training of specialists. Undue weight is attached, particularly by the laity, to higher degrees and diplomas; and the extent and quality of teaching varies from one university to the next and from one department to another. Last week, in the annual address to the Institute of Laryngology and Otology, London, Sir Francis Fraser, director of the British Postgraduate Medical Federation, suggested that the remedy lies in the competitive selection and progressive training of candidates, who before applying for a specialist hospital appointment should reach a standard imposed by their colleagues. As he pointed out, the Royal Colleges and the associations of specialists have recommended at least five to six years' postgraduate experience for each intending specialist, of which the first one or two years should always be devoted to general medicine or general surgery, and a year or more should be spent in scientific training and laboratory discipline. The programmes include higher degrees and diplomas, but these are not to be regarded as qualifying men as specialists.

Sir Francis Fraser favours progressive selection from the stage of senior house-appointments onwards—a process facilitated by the larger grants for medical education and the introduction of the National Health Service. The first stage of a registrarship should if possible be in a teaching hospital, but since the clinical material in a university teaching hospital is regulated by the needs of the undergraduate the registrar should go elsewhere for fuller practical experience, spending his second year perhaps in a regional hospital, or a special department, which has been approved for the purpose and where teaching can be supervised. The third stage of training will depend on the candidate's previous experience and aptitudes: he may return to his teaching hospital; he may be attached to a professorial department; or, if his bent is towards the treatment and management of patients, he may seek a further period of clinical experience. At some time all should have the chance of travelling to other centres in this country or abroad.

It is debatable whether courses are of much value to fully trained men, except to those who find it hard to synthesise their knowledge; certainly they cannot take the place of hospital appointments with graded responsibilities. The usual type of organised course is designed as an introduction to a specialty, but unfortunately it often enables candidates to obtain diplomas. Some of these diplomas should be regarded as simply qualifying their owners to start specialist training; few of them indicate that training has been completed. There is real danger, in Sir Francis Fraser's view, that London may come to be regarded as a purveyor of diplomas; and he proposes that the Royal Colleges and the university should work together to ensure that these higher qualifications take their proper place in the training. The experience in London, with its specialist teaching hospitals, is, he said, that the standard of teaching is generally higher in the branches where there is no diploma. The specialist hospitals are the basis of the institutes now being built up by the university, and as soon as possible the university will be asked to appoint a professor or reader to each.

Sir Francis sees a place for two types of course in each specialty. First, there may be a course, lasting about six months, in the fundamentals, with practical work supplemented by group discussions, lectures, and demonstrations: it should be preparatory and educative rather than vocational, and all those attending it should be able to go to central lectures in the basic sciences. Secondly, there should be courses designed to coö and systematise practical experience. An adv revision course of this second sort, lasting some weeks, makes heavy demands on teaching staffs, and should be attended only by those advanced enough benefit.

FILLING THE GAP AFTER PNEUMONECTOMY

AFTER pneumonectomy it is found paradoxically mediastinal shift is greater in uncomplicated cases, in the less fortunate ones where infection necessitat thoracoplasty to reduce or obliterate the empy cavity. The sequel in the uncomplicated case is "co pensatory" emphysema with reduction in exerc tolerance and, later, impairment of general activ The outlook is more hopeful when in the absenc infection and drainage the cavity gradually fills serum, for this provides splintage and when it bec organised draws the mediastinum slowly towards chest wall, allowing a maximum time for pulmo adjustment with a minimum effect on the great ve Unwilling to undertake elective thoracoplasty a pneumonectomy, thoracic surgeons occasionally in serum or blood into the empty pleural sac with relativ successful results.

Other media for prosthesis, such as liquid para intrapleurally or paraffin wax extrapleurally, have be tried and discarded. Johnson et al.,[1] in animal experiment found a shaped hollow metal-box prosthesis (of zirconium a stainless metal) too unwieldy and mildly irritati After total pneumonectomy in the dog they inser one-inch hollow balls of methyl methacrylate (lu into the pleural cavity, taking care to remove as m air as possible when closing the chest and drawing excess fluid by thoracentesis next day. Of 16 do 3 died three weeks later, from causes unrelated to t operative interference, and the remainder were ki at intervals to study the reactions of the pleura. Th reactions were negligible, consisting of minimal fibroblast proliferation and round-cell infiltration. At two month the longest interval up to the date of the report, the ball were free and evenly distributed throughout the pleur cavity and the fluid present occupied the intervenin spaces; mediastinal displacement was effectively prevented and the remaining lung had not become overdistended. Wilson and Baker[2] have also studied th effects of methyl methacrylate on pleural and extrapleural tissues in animals, and have used hollow ba of this material to fill the extrapleural cavity after extrapleural pneumonolysis in patients with pulmonary tuberculosis. Provided preliminary tests for individual sens tivity to the acrylic resin are applied, a prosthesis made of this plastic may be successful in preventing overdistension of the remaining lung after pneumonectomy in man.

MISUSE OF THE EMERGENCY BED SERVICE

WE have lately published several examples of what seemed to be gross abuses of the Emergency Bed Service—the bureau set up by the King's Fund to simplify and hasten the admission of urgent cases to London hospitals. The complaints come from the hospitals receiving patients via the E.B.S. from practitioners or (in one case) from another hospital, and *Dr. Herbert's* letter of Oct. 11 shows that some of the trouble arises from the well-known faculty of patients to change or lose their symptoms on their way to hospital. But there are also cases where doctors suppress undesirable clinical features and emphasise desirable ones because they know that with the present shortage of beds the patient will otherwise have little chance of getting into hospital at all.

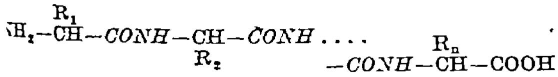
2. Wilson, D. A., Baker, H. *Surg. Gynec. Obstet.* 1946, **82**, 735. Wilson, D. A. *Surg. Clin. N. Amer.* 1946, p. 1060.

practice of "dumping" by ambulance, at one time opular way of shifting responsibility for the chronic in London, has largely been checked by limiting the t to order a free ambulance to the hospital underng to admit a patient. Places intended for the nic sick are now very scarce. It is understandable, efore, if doctors are occasionally tempted to embroider history and findings so as to bring the patient within scope of the well-oiled machinery intended for urgent s. When, however, as Dr. James (Oct. 11, p. 562) es, such embroidery extends to denying a history of rhœa in a child destined for a premature-babies l there is a danger of undermining the confidence which the E.B.S. scheme stands. The staff of the .S. ask for full details of each case submitted to n, and base their search for a bed on the replies they ive. They can serve the best interests of patient, or, and hospital only if they can rely on the good of all parties. There will always be borderline s, because the definition of an emergency depends on point of view—what looks desperately urgent in a cottage at 2 A.M. may be a case for routine investi-on next day in a hospital bed—but as Dr. Herbert : "If occasionally a case is sent which does not it immediate attention, it is better thus than that s should be neglected for fear of criticism from the lent staff."

SYNTHETIC PROTEIN ANALOGUES

ROTEINS are composed of long chains of amino-acids d together by peptide links. These peptide links ONH—) are formed by the elimination of water reen the carboxyl (COOH) group of one amino-acid the α-amino group (NH_2) of the next amino-acid. no-acids may be written in the general form $CHNH_2—COOH$, where R is methyl in the case of ine, *p*-hydroxybenzyl in tyrosine, and so on. The cture of the protein chain may therefore be written :



$$\mathrm{NH_2{-}\overset{R_1}{CH}{-}\mathit{CONH}{-}\underset{R_2}{CH}{-}\mathit{CONH}\ \ldots\ {-}\mathit{CONH}{-}\overset{R_n}{CH}{-}COOH}$$

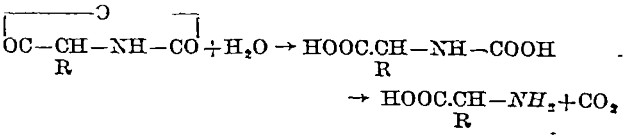
urally occurring proteins have molecular weights ing from a few thousands to a few millions—that is, e contain 100 or so amino-acid units in the molecule, rs 100,000 or more. The different proteins con- different proportions of the naturally occurring no-acids, of which some 25 are known.

he joining up, in the laboratory, of amino-acids by ns of the peptide linkage to form peptides requires rtain amount of chemical tactics. This has been ible since the beginning of this century, when Emil her devised several methods, and more recently gmann and Zervas have introduced their elegant obenzoxy method. By repeated application of his ous methods and with much labour Fischer in 1907 eeded in joining together 18 amino-acids to form "octadecapeptide" which had some protein-like perties.

e are now in the age of haste and plastics; the er have achieved such social significance that in lern mythology a shower of nylons would replace shower of gold. One product of research into plastics be a short cut to the laboratory synthesis of protein- bodies. Plastics of the "superpolyamide" type, h as nylon, consist of very large molecules containing ltiple peptide linkages. Nylon itself, synthesised by others in 1935, is made by heating hexamethylene mine with adipic acid, and it has the structure :

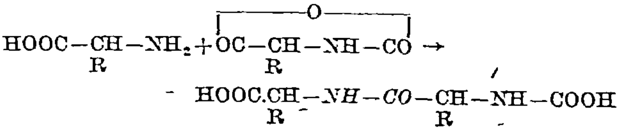
$$\mathit{-NHCO}-(\mathrm{CH_2})_4-\mathit{CONH}-(\mathrm{CH_2})_6-\mathit{NH-CO}-(\mathrm{CH_2})_4-\mathit{CONH}-(\mathrm{CH_2})_6-\mathit{NHCO}-$$

nce long chain compounds with multiple peptide s can be obtained by polymerisation processes. Recently Woodward and Schramm,[1] of Harvard University, have found that bodies more nearly related to proteins may also be obtained by polymerisation reactions. Leuchs and Geiger[2] had shown that the anhydrides of N-carboxyamino acids lose CO_2 in the presence of water and yield solid insoluble substances, obviously polymers. Woodward has realised that these are peptides of high molecular weight. Whereas the anhydrides of the N-carboxyamino acids are crystalline bodies stable in the absence of water, the free acids which they yield in the presence of water break down, losing CO_2 and forming a new free amino group.



$$\mathrm{\overbrace{OC{-}\underset{R}{CH}{-}NH{-}CO}^{O} + H_2O \rightarrow HOOC.\underset{R}{CH}{-}NH{-}COOH \rightarrow HOOC.\underset{R}{CH}{-}\mathit{NH_2} + CO_2}$$

The free amino group enables the product to combine with a second molecule of anhydride forming a peptide :



$$\mathrm{HOOC{-}\underset{R}{CH}{-}NH_2 + \overbrace{OC{-}\underset{R}{CH}{-}NH{-}CO}^{O} \rightarrow HOOC.\underset{R}{CH}{-}\mathit{NH{-}CO}{-}\underset{R}{CH}{-}NH{-}COOH}$$

The resulting substance is unstable and loses a molecule of CO_2 from the $-NH-COOH$ group, thereby generating a free amino group, which enables it to combine with a third molecule of anhydride. The process thus goes on, building up a chain of the general structure (I) possessed by proteins. Woodward and Schramm dissolved together N-carboxyleucine anhydride and N-carboxyphenylalanine anhydride in benzene containing a trace of water. The reaction proceeded for a fortnight at room temperature, the solution gradually becoming more viscous. The solution was then cast, leaving a clear tough film. The molecular weight of the product, a peptide of leucine and phenylalanine, was several million, indicating that not less than 10,000 amino-acid residues were present in the molecule.

The value of this remarkable discovery to the protein chemist is not yet certain. The protein analogue formed differed from naturally occurring proteins in being soluble in benzene. This was because the two amino-acids of which it was composed have non-polar R groups—i.e., benzyl in phenylalanine, *iso*butyl in leucine. It remains to be seen whether the process is applicable to the amino-acids containing polar R groups which enter so largely into the composition of proteins. Even if it were found possible to copolymerise several amino-acids, would it be possible to control the order in which the different amino-acids linked up to form the chain? This order is presumably of great importance, and if it were not controlled the product would be a mixture of a very large number of different peptides. As matters stand it seems that Woodward's discovery may be of greater value in plastic technology than in protein chemistry, but in the long run it may open up new fields of protein research.

It is unlikely that living tissue synthesises protein by polymerisation reactions of this sort. Recent American work points to a possible mechanism for peptide bond synthesis in vivo. Synthesis of hippuric acid from benzoic acid and glycine and of *p*-aminohippuric acid from *p*-aminobenzoic acid and glycine in liver homogenates has been studied by Borsook and Dubnoff[3] and by Cohen and McGilvery.[4] These workers found that adenosine triphosphate promotes the synthesis, and it is suggested[4] either that the aromatic acid forms a

phosphate of the energy-rich type[5] which then reacts with glycine releasing phosphoric acid, or alternatively that the glycine forms an energy-rich phosphate which then reacts with the aromatic acid. Again, the amide group of glutamine is analogous to a peptide link, and there is some indication that an energy-rich phosphate of glutamic acid is an intermediate in the enzymic synthesis of glutamine from glutamic acid and ammonia.[6] If it is confirmed that this type of mechanism is involved in peptide bond synthesis in these simplified systems it may conceivably also be involved in the synthesis of some of the peptide bonds in proteins.

OPERATIONS ON INFANTS: THE MOTHER'S PART

MANY have advocated that when an infant needs an operation his mother should be admitted to the hospital at the same time, so that she may continue to tend him; and the plan has been successfully tried in some parts of England, notably in the department of child health at Newcastle. In New Zealand the principle has been carried a step further at the Bassam Clinic, outside Wellington. In a recent account[7] of this experiment Dr. Cecily Pickerill, who, with her husband, Mr. H. P. Pickerill, F.R.A.C.S., is in charge of the clinic, refers to the dangers of cross-infection to which infants undergoing plastic operations are exposed in a general ward. A cleft-palate case, for example, offers a raw nasal surface to all the organisms present in the air. The Pickerills believe in early operation for this malformation and such others as hypospadias, epispadias, angioma, and syndactyly, because successful treatment in infancy allows the child to grow up without a period of disability or disfigurement, and because the baby is much more passive under plastic surgery than the growing child, and hence is less liable to spoil results. Yet the dangers to all such infants in the wards of a hospital are very great: not only may the wound slough from local infection, but the child may sicken or die of a general infection. At the Bassam Clinic they have reduced this danger by admitting each mother, with her baby, to a small bed-sitting-room of her own. This is comfortably and pleasantly furnished, containing besides the mother's bed a crib or cot for the baby, an easy chair, an electric fire, and what other appropriate furniture is needed. Here the mother can look after the baby exactly as though she were at home. She has the companionship of other mothers in neighbouring rooms, and can enjoy the garden where the babies take the air in perambulators; freed from household responsibilities, she can rest and give her whole care to the baby. All dressings are done in the theatre, under aseptic conditions, the children usually being put under short light anæsthesia for the purpose. This means that strapping and dressings can be removed deliberately and carefully, and the area cleaned without pain to the baby. Chances of cross-infection are reduced to a minimum, and the child suffers no emotional shock. Moreover, only a few skilled nurses are needed: the mother does all the routine tasks for the baby which take up so much nursing time in a hospital. She also keeps the weight chart, and of course feeds the baby; and, as no child with a falling weight is sent for operation, this means that the mother has responsibility and incentive beyond the ordinary—an important point, since the feeding of a child with a double hair-lip is at best tedious, and would engross a great part of a nurse's time. Operations are done in several stages, on the principle that babies stand several small operations better, and with less postoperative shock, than one or two more extensive ones. The Pickerills note their experience that preoperative and postoperative sedation is hardly necessary: the best sedative for any the mother.

The clinic, built with the sanction and help of New Zealand Health Department, has been running five years; during that time there has not been a case of cross-infection, local or general, and not a slough or case of dehiscence.

SOCIAL WORKERS

CORRESPONDENTS have recently discussed the typ social worker needed to help the general practitio Dr. Beryl Harding[1] has suggested a service of volun workers, supervised by trained welfare workers. Marjorie Steel,[2] of the Institute of Almoners, notes the health visitor is "the health worker in the setting" and quotes a letter from Miss Amy Sayle, Women Public Health Officers' Association, to Times on Sept. 12, in which she spoke of the visitor as being the future general medical social for the whole population. In our present issue C. E. A. Bedwell (p. 594) reminds us of the played by the district nurse as the general practitio coadjutor.

The almoner of course has her own sphere, special type of social worker in hospital; and functions of her department have recently been set in a statement issued by the council of the Institute Almoners.[3] Her work, they say, falls under three ma heads: medical social work directly concerned with doctor's investigation and treatment of the pati illness; other work within the hospital in which knowledge and skill of a trained social worker is ne (including teaching, research, and the planning facilities for patients); and coöperation with agencies concerned with the social aspects of medici She will also help to plan details under the N Health Service. She should try to have at least interview with every patient in the hospital wards attending the clinics, should consult often with medical and nursing staff, and should keep the social histories readily accessible to the doctors. An social worker with a place in the health team is obvi the psychiatric social worker.

The difficulty in the past has been that the p tioner, though he has been in close touch with district nurse, could seldom work in direct with the health visitor, the psychiatric social worker, the almoner. Eventually all such workers will pr have some connexion with the health centres, and might meet some of Dr. Harding's requirements. In further letter this week she refers to the important point made in the *Times* of Oct. 8 by Dr. H. Morley F as chairman of the Nursing Recruitment Committee—namely that hospitals in their present straits cannot afford to lose so many of their trained nurses to public-health services where they are not concerned with the care of the sick. Dr. Fletcher objects to the W Party's unrealistic statement that "the proper stage the estimation of sick nursing requirements should subsequent to the estimation of the optimal requirements of the health nursing services." The *Times* last Tuesday wisely suggested an inquiry into the work and training of the health visitor which might help to show what particular functions each kind of worker should perform in the medical social field.

RELEASE OF DOCTORS FROM SERVICES.—The Central Medical War Committee have been informed by the Air Ministry that Royal Air Force medical officers in age-an service group 64 will be made available for release in December, 1947.

ARMY HEALTH AND MEDICAL ADMINISTRATION

H. S. Gear

M.D. Witwatersrand, D.P.H., D.T.M. & H.

PUTY CHIEF HEALTH OFFICER, UNION OF SOUTH AFRICA

RING the late war the medical organisation of the monwealth armies was efficient in its provision of cal care. "The sick and wounded have been nded with devotion, efficiency, and unprecedented ess, while the high level of physical and mental th in the Forces owes much to an improved practice preventive and social medicine."[1] The hygiene ch successfully controlled preventable disease and loped and maintained the fitness of the Army during Middle East, Mediterranean, and European camns; moreover, its advice was heeded by the General f and administrative services on such subjects as ons, clothing, equipment, and camp siting. Neveress there is some justification for inquiring whether present system provides the best means for ensuring the Army receives the best possible information health and medical questions.

he main concern of the average medical administrator till for the patient—wounded or sick—and hence is chiefly interested in administering the medical rices proper. But one of the two cardinal functions director of medical services is to estimate all factors cting the health of the army and inform the comder of the force of any measures necessary to counterharmful influences or to enhance or introduce eficial ones. Is the expert in hygiene given a rôle responding to the importance of this task ?

HYGIENE AND THE ADMINISTRATOR

Army medical administrators have been basically ined as clinicians. As students they have been steeped the traditions and atmosphere of curative and hospital dicine. Their concern has been with the sick— rticularly the sick in hospital. As students and actitioners they have rarely had to reflect on the dinary daily lives of their patients in work-place, me, or society, and so find it foreign to think of the ldier in his daily activities.

Again, medicine both in peace and war is activated the deep emotional forces of humanitarianism. Thus e injured and the sick always have first claim on the elings and instincts of medical officers. This care of tients during campaigns must be a major concern of a nically trained administrator, especially as the soldier's orale is maintained by the knowledge that in distress will be succoured by an efficient and sympathetic edical service.

To the influence of training and humanitarian feelings added the deep satisfaction given to the medical dministrator by "running his own show." He is ctively occupied in directing his own hospitals, field mbulances, medical laboratories, and staffs of medical fficers, nurses, and orderlies. Indeed, it is by the fficiency and adequacy of his hospitals and clinical fficers rather than by his hygiene service that he is udged by his peers and by the General Staff and dministrative services.

Such are the influences which have combined to mphasise the curative and clinical sides of military medical organisations. Under existing conditions their dministrators could not but become absorbed in directng, training, allocating, and moving medical units, medical personnel, patients, and medical stores, and ttention to these tasks has sometimes prevented them from giving adequate consideration to the "hygiene" needs of the Army. In their tours during the war they usually found it impossible, for example, to visit other than medical units: only seldom was an inspection made of a battalion in the line, a lines-of-communication camp, a depot, a workshop, or a cook-house by other than hygiene representatives of medical headquarters. Thus the director of such a headquarters could rarely get first-hand knowledge of the factors contributing to an army's efficiency and well-being. He could know little directly of the many medical problems associated, for example, with armoured fighting vehicles, or the use of labour in large modern vehicle-repair or other workshops, or with equipment, clothing, food, recreation, or transport. Yet it is these factors which largely produce the sick and injured, and so fill the hospitals.

Some specialised services, such as Mountain Warfare and Combined Operations, were faced with serious problems in such fields; and as the orthodox methods could not always help them sufficiently, they tended to appoint their own medical advisers. Such ad-hoc arrangements, detached from the general medical services of an army, must be considered undesirable. They must be avoided by the appropriate development of the advisory branches of the existing organisation.

HYGIENE AND THE UNIT MEDICAL OFFICER

Theoretically, it should have been possible for unit medical officers at subordinate levels to give equal emphasis to both aspects—clinical medicine and hygiene. It has been one of the sad revelations of the war, however, that the average unit medical officer is often uninterested in other than clinical duties. Often the daily sick-parade has constituted the beginning and the end of his duty. He is not to blame. His view of medicine is that fixed by his medical school. Though the Army has usually put him through short courses on military medicine, in which broader responsibilities have been brought to his notice, unhappily the results of such preparation have not always been impressive in hygiene fields. The unit medical officer, on completion of his sick-parade, rarely went on to study the health factors influencing his men in all their activities. Some, however, knew how the rations should be drawn, stored, and prepared; how equipment and clothing met the needs or were inefficient, irritating, or even harmful; how the distribution of duties left men fit or exhausted; how mail, parcels, news, and amenities affected morale and sickness; how positive interest in welfare contributed to the unit's success—in a phrase, how hygiene "paid."

A partial explanation of the lack of interest shown by medical officers lies in the inclusion in most unit establishments of so-called hygiene personnel. Generally such personnel consists of non-technical non-commissioned officers or men given a rudimentary training in sanitation and water duties. Their presence has led many medical officers to wash their hands of any "hygiene" responsibility.

A final contributing factor to this attitude is that the junior takes his cue from the senior. These juniors have been aware of the dominance of sick-bays, first-aid posts, lines of evacuation, stretcher-bearers, and medical panniers in the plans and inspections of their medical administrative superiors. Naturally, they too had to give prominence to these matters in their own work.

HYGIENE AND THE CONSULTANT

The position and function of consultants and advisers deserve some attention in connexion here.

During the war any lack of direct administrative power was more or less counterbalanced by their possession of special privileges. They held extraordinarily high rank, and they had the right to direct communication with their senior consultant colleagues in their respective home headquarters—e.g., the War Office in the case of U.K. Forces. Consultants were mostly prominent members of the profession brought into the Army from civilian life. Their ignorance of Army procedure and conditions occasionally made them unsympathetic to the men carrying the real burden—i.e., the administrators, who were usually Regulars. This situation might have created unending friction, and it is proof of the adaptability and good will of both groups that so much harmony and coöperation existed. Nevertheless, if the full purpose of army medical services is to be achieved, some of the anomalies existing in the present system of providing consultants must be removed.

High rank was apparently given to ensure that the views and opinions of the consultants were not lightly rejected. However, it seems that the other extreme was reached. Quite youthful brigadiers, consultants in very limited fields, had the power to exaggerate the importance of their subjects and press their claims unduly on less exalted administrative medical officers. Such administrators were sometimes awkwardly placed in having to reject unsuitable and unreal advice and recommendations from such sources. A suitable rank for advisers is necessary, but it should not be above that of the administrators who are advised. Here it may be interjected that there seems to be no reason why surgery should be specially glorified by having a consultant of higher rank than his medical colleague!

Having a large group of high-ranking clinical consultants attached to each medical directorate was another contribution to the tendency towards concentration of the medical services on curative medicine to the relative neglect of hygiene. As in the previous groups mentioned, these consultants absorbed in clinical work could rarely initiate investigations of the everyday problems of an active army. Yet such problems were legion—topees and effects of the sun; desert glare and sun-glasses; shape, size, and weight of weapons in relation to human capacities to use them; the effects of noise; hours of work in repair depots and in transport companies; acclimatisation factors. Advisers and consultants were as much inclined as their administrative colleagues to gravitate towards clinical medicine.

NEED FOR IMPROVEMENT

In the Middle East campaigns, as has been shown in an earlier paper,[2] the first six most important causes of hospital admissions—in other words the main causes of man-power wastage—were largely preventable: they were diseases of skin and areolar tissue, diseases of the alimentary system, accidental injuries, dysentery, malaria, and venereal diseases. The prevention of such conditions in an army will only be fully effective when the army medical services—administrators, consultants, and unit medical officers—seek out the entire epidemiology of these diseases. This presupposes a knowledge of the soldier in all his doings and not merely when he is recumbent on a sick-bed. Such knowledge is the essential basis for the more positive modern purpose of medicine of enhancing health and vigour. Further, this improvement in the hygiene services must be accomplished without in any way diminishing the high excellence of the curative services.

PROPOSALS FOR A BETTER-BALANCED SERVICE

(1) No senior army medical administrator should be appointed who is not trained and experienced in hygiene. Hygiene is here used in its widest and most proper sense to include considerations of all influences on the health of man as an individual and as a member of a community. Such officers, by training and experience in law, statistics, epidemiology, preventive medicine, and public administration, are accustomed to take into account *all* factors affecting the health and efficiency
community and to dispose of their resources ac
This will not mean neglect of curative and
services, for the health administrator is accustom
handling curative and institutional services as part
parcel of his means of improving the health of the
munity. Further, he has that perspective, given
a philosophy based on vital-statistical and epid
logical grounds, which should ensure the optimum
of clinical facilities as well as their complete inte
with other agencies. One index of a training in
fields is possession of a qualification in State
or public health.

(2) At the level of the unit—battalion,
depot, barracks—the medical officer should fulfil
hygiene as well as his clinical functions. This
depend on emphasis given to this subject not
his preparatory training but also by his seniors in
supervision and inspection of his work. It is not
much new knowledge is required of the medical
but rather a concern by him in his unit at all times.

(3) The curative services, with their personnel
institutions, should become the source of much of
expert advice and of such special facilities as labor
investigations needed by unit medical officers practi
preventive and social medicine. The unit medi
officer following up problems of gun-sights, battle noi
agents inimical to the skin, morale, &c., should
expert assistance, and the obvious source in most
would be the medical and surgical specialists on
hospital staffs. It should be brought home to
specialists that such an extramural service is expe
of them.

(4) As a corollary to the above, consultants
advisers should extend their interests and tours to ca
barracks, workshops, and battlefields, to assess and
on the medical aspects of the multitudinous pr
there to be found influencing the efficiency and
being of the Army. Obviously, the arrangements
using clinical services as indicated in these last
recommendations will be the responsibility of the
medical administrators. With the appointment
hygiene-minded administrators, this should be a
development.

(5) The panel of consultants attached to the m
branch of a general headquarters should be increased
include expert advisers on such subjects as
physiology, biochemistry, nutrition, industrial
water and sanitary engineering, health education,
the prevention of any diseases of special importance.
present the two hygiene administrators on such a head
quarters have to cover this vast complex technical
with very little direct consultation available to them
except in malaria control.

(6) Even with the above changes there is not a
assurance that the commander of a force, especially in
secret planning and operations, will be au
informed of the importance of these medical fac
The only solution appears to be the inclusion of
director of medical services in the immediate staff of
commander-in-chief.

(7) The optimum benefit of the recommendati
given here, however, will only follow a change in emp
in medical education. Preventive medicine and h
(including social medicine) have yet to be accorded th
due in most Commonwealth medical schools.
needs of organised medicine, whether civil or milit
demand recognition in the curricula of these schools.

COMMENT

I wish to make it clear that criticism is not
directed at the broad principles on which the A
medical services have been operating. In theory
are good. For example, the regulations governing

---

[2] Richmond, A. E., Gear, H. S. *J.R. Army med. Cps*, 1945, 85, 1.

ices have, in principle, emphasised the prevention lisease and the duty of medical officers to advise on preservation of health. It is the unequal emphasis practice and in administrative control and detail n to the curative duties to the neglect of hygiene which uestioned.

uring the recent campaigns the hygiene branch had nore complicated and difficult task to accomplish n its sister clinical services. "Hygiene" gave the h Command fitter and more vigorous armies than in previous war, but it did so under serious handi-. If these can be removed, the army of the future not lack the soundest health and medical advice in ts activities, without any reduction in the excellence he curative and clinical services. Whatever new ructive agents may be developed, this balanced th and medical military organisation will be essential. hether armies will be needed in the future or not, rience in large-scale administration is surely valuable pertinent to countries now planning national medical ices. The traditional, emotional, professional, and al eminence given to the surgeon and physician is rved; but only when the medical administrator ned in hygiene is equally recognised will an integrated, d, comprehensive, and balanced medical and health ice be achieved. Some of the community needs -bed or consulting-room attendance some of the time; the community needs health guidance all the time.

POSITIVE HEALTH IN THE ARMY

BRIGADIER RICHMOND'S ADDRESS

N a Chadwick lecture delivered in London on Oct. 7, gadier A. E. Richmond, director of hygiene, War Office, gested that "the medical profession has marched much in the gloomy vales of disease." The achieve- nt of positive health was, he said, essential to the Army: nfluenced morale, and without it the highest pitch of ciency could not be achieved. During his one year's ning in the Army the National Service recruit must shown what he could do for his own health and for t of others, and what could be done by others for him.

f the men examined by civilian medical boards ween June, 1939, and March, 1947, and excluding se with gross incapacity who were not called up for mination, 65·7% were placed in grade I; 15·2% in de II; 8·8% in grade III; and 10·3% in grade IV. third of the rejections were due to disorders of the diovascular system, of locomotion, and of the ears, h of which accounted for just over 10%; nervous tability or mental disease caused 7·4% of rejections, l diseases of the lung, other than tuberculosis, 6·95%.

f 5169 recent recruits to the Army, 85·24% were ced in category A1, and 7·06% in lower A categories; 0% were placed in category B1, and 1·05% in lower categories; while 0·6% were placed in category C1 C2. The common causes for recruits being placed in egory B were: ear diseases (9·4%), diseases of the piratory system (7·9%), defects of the abdominal gs (7·9%), cardiovascular disorders (5·1%), and eases of the central nervous system (4·5%). Of all ruits, 3·5% needed psychiatric guidance on the form Service employment.

The maintenance and advancement of health must be ieved largely by attention to the form of employment d by ensuring that the employment was suitable to e man's gifts. Thus selection and categorisation were the first importance. The PULHEEMS system of tegorisation, already in use by the Canadian Army, s to be adopted by all three Services and would be ed by the Army from the beginning of next year.

For substandard recruits physical development centres d been started before the late war; and they were eatly expanded during the war. Of 35,000 men dealt th in courses lasting eight weeks, 71% had been raised category, and of these 69% had been placed in tegory A1. There was now one centre, dealing with ,000 recruits each year. The task of making these ung men fit should, suggested Brigadier Richmond, undertaken about school-leaving age.

At primary training centres drill occupied at first 14% and later 9% of the recruit's training hours. Drill was important, for it taught obedience, cohesion, precision, carriage, and self-respect. Physical training occupied 17% of the training hours; its object was "to get the man fit and to keep him fit, and to refit the convalescent." The soldier must be imparted with the will to be fit, and physical training must be both purposeful and recreational. At the end of his primary training the recruit had an increased exercise-tolerance, and greater endurance, control, coördination, alertness, and quickness of action; and his weight had risen by 6–8 lb.

For the recruit's training in hygiene selected instructors from training centres attended special courses at the Army School of Hygiene. At the primary training centre the recruit received instruction in personal hygiene, and at the corps training centre instruction in communal hygiene. Other ways in which the young soldier was guided towards positive health were through attention to his moral welfare, through the "C.O.'s hours," and through the "padre's hours."

The trained soldiers' physical and mental health were cared for by their officers, who were trained in man-management and hygiene; by the medical service; and by the Army's psychiatric organisation. Environmental hygiene was also not neglected: included under this heading were accommodation, food, water, clothing, welfare, recreation, and education. Personnel research was receiving increasing attention: by this was meant the study by physiological, psychological, anatomical, and other methods of means by which operations could be carried out with the greatest possible efficiency, safety, and comfort; and the adaptation of vehicles and other mechanical devices to the needs of their users.

CONFERENCE ON FOOD AND DRINK INFECTIONS

A ONE-DAY conference and exhibition on food and drink infections, organised by the Central Council for Health Education at Friends House, Euston Road, London, on Oct. 11, brought together 1100 delegates—medical officers of health, bacteriologists, chairmen of public-health committees, and sanitary inspectors representing most local authorities in the country, together with representatives of the food and catering trades.

Lord WOOLTON, president of the C.C.H.E., in opening the conference, said it was not known how many are killed each year by food and drink infections, but he instanced the 1500–2000 children who die annually from bovine tuberculosis, the 200–400 deaths from typhoid and dysentery, and the 3000–4000 infants, mostly artificially fed, who succumb to enteritis. In addition there is evidence of a greatly increased incidence of bacterial food-poisoning associated with the increase of communal feeding. A large part of this kind of infection is avoidable—and this point was also emphasised in a message from the Minister of Health—by pasteurisation of milk and by a much higher standard of cleanliness of personnel and equipment, an objective attainable even in these difficult times.

SOURCES OF INFECTION

Sir WILLIAM SAVAGE said that our knowledge of the problem has been growing steadily in the past 20–30 years and the time has now come for that knowledge to be applied on a much larger scale. Most of the food-borne diseases are due to infection with specific germs, though the occasional chemical poisoning—arsenic, lead, antimony, cadmium, zinc—must not be overlooked. The reservoirs of these germs are man in the case of typhoid and dysentery, mostly animals in the salmonella infections, and the soil in the case of botulism, a rare infection in this country. When the reservoirs are known the paths by which the germs can be transferred to consumable foods become obvious, but it is important to recognise which foods are most likely to become dangerously contaminated. Outbreaks are often traced to cooked ham but rarely to fresh pork; bread is practically never incriminated because it does not encourage bacterial growth. To control food-borne infections we must see that our food is itself free from disease; although there has been a concentration of slaughterhouses to some 500 centres, meat inspection is still far from satis-

factory and a large amount of raw infected milk is still being consumed. Large-scale handling and preparation of food needs expert supervision but it is in the retail distribution that most trouble arises. While improvements in kitchen and personal hygiene are urgently needed, Sir William Savage recounted some of the difficulties: shortage of crockery and cutlery, and of washing facilities particularly during rush hours; staffing problems; inadequate cold storage; and wash-basins inconveniently placed if present at all. He did not favour regular medical examination of food-handlers but suggested that all cases of illness in catering establishments should be reported to the medical officer of health. He thought we should determine which are the essential matters in food hygiene and make our legislation more precise and practical so that there could be a better control over hygiene in the kitchen. To this end, he suggested, a national committee of experts and administrators might be appointed.

Prof. G. S. **Wilson** remarked that ptomaine poisoning from decomposition of food is a myth and that the various types of food-borne intestinal infection—acute gastro-enteritis, bacillary dysentery, and enteric fever—are due to contamination of the food, usually undetected by the senses, with specific germs. The increasing tendency to communal feeding means that the contamination of one article of food may involve 200–300 workers or school-children and not just 2–3 members of a household. The source of the infecting germs is, in typhoid and dysentery, the fæces of cases and carriers, and since it is often impossible to say who may be a carrier, and since contamination of the hands with bowel germs is practically unavoidable, hand-washing after use of the W.C. should become a universal social habit. The salmonella food-poisoning group is found in a variety of animals—cattle, pigs, poultry, vermin—and as an example of how infection can be spread he instanced the recent outbreak in Essex traceable to an infected pig in a slaughterhouse with secondary contamination of pressed beef in the butcher's shop. The staphylococcus, which has now been incriminated in many food-poisoning outbreaks involving ice-cream, cheese, trifle, gelatin-glazed sausage meat, &c., is derived from the human nose and skin, so with a high nasal carrier-rate and the frequent occurrence of skin infections and septic sores among food-handlers the opportunities for staphylococcal contamination of food are great. Foods in which rapid bacterial growth is most likely to occur are milk and milk products; synthetic cream, ice-cream, and custards; made-up dishes such as pies, brawn, pressed beef, and cooked sausage; soups, gravies, and stews; and canned foods *after* the tin has been opened. Professor Wilson gave illustrative examples of outbreaks of food-poisoning and discussed some of the principles of prevention.

Mr. L. H. **Lampitt**, D.SC., chief chemist of the Lyons Laboratories, pointed out that a great deal of self-education in food hygiene has been done by the large catering firms and that no large-scale outbreak of food-poisoning has been attributed to his firm in the past twenty years despite a staff of 20,000 and a service of some half a million meals a day. They have adopted a three-tier system of education: inspectors are specially trained to supervise production and investigate complaints; all reports of inspectors are available to managers of departments, to whom faults of staff are also reported; and simple demonstrations are given to staff about personal hygiene and about the dangers of direct or indirect contact between raw and cooked foods. The main obstacles to a higher standard of food hygiene are human inertia which requires constant correction, the present standards of behaviour which make good discipline difficult, and supply problems in equipment, staff, and materials. A great deal of work has been done on the physics and chemistry of food to ensure a better micro-biological control—e.g., on heat penetration and lethal heat points, moisture and salt content, and hydrogen-ion concentration.

CONTROL OF INFECTIONS

In the afternoon session, Dr. **Robert Cruickshank**, director of the Central Public Health Laboratory, Colindale, discussed four measures in the control of food-borne infections—education of the food-handler; public-health supervision of catering establishments; protection of food against bacterial cont sanitation of food utensils and food-con described the progress being made alone the U.S.A. Education is better than comp courses of three lecture-demonstrations by a specially trained sanitary inspector, medical health, and bacteriologist have been organised American cities with the help of the U.S. Publ Service, which supplies films, lantern slides, as described in their pamphlet *Guide to Safe Food* A beginning has been made with similar cours sanitary inspectors, school-canteen supervisors, and personnel among food-handlers in this country. tunately the rank and file of the food-handlers are poorly paid and of low-grade intelligence, so is difficult, but the introduction of a minimum a greater realisation of their importance to the health may attract a better grade of worker. is made under the Food and Drugs Act, 1938, for vision of food-handling establishments, but the legislation has not gone far enough, and, what is sanitary inspectors do not have time to pay visits which might stimulate the management and to higher standards of food hygiene. Consi should be given to the training and appointment of officers, male or female, whose duty it would be supervise catering establishments and organise tional courses in food hygiene.

As regards medical supervision, existing regul prevent a typhoid carrier from being a food-handl a water-works employee, while sufferers from inte infections or sore throat can be debarred from hand milk. But a much wider provision of medical ca required for all food-handlers so that any infective can be immediately reported and properly bacteriologically as well as clinically. The effect of and suitable temperature in allowing bacterial plication in prepared foods indicates the urgent much more cold storage, particularly in res canteens where for one reason or another food has to be prepared and cooked hours before it is eaten. food manufacturer should also aim at minimising manual handling of food by the greater use of machi Flies can be eliminated by screens and D.D.T. and ve kept at bay by a kitchen cat.

Improperly cleansed crockery and cutlery may p some part in the spread of intestinal and respira infections, and much progress has been made detergents and a reliable dish-washing drill in pr such a risk. Washing either by hand or machine is out at temperatures of 120–140°F, with detergent or sulphonated alcohol to ensure proper cleansing of utensils; this is followed by rinsing for half a minute 170–180°F, which sterilises the utensils and obviates need for wiping crockery; clean dish-cloths must be for cutlery. Similar treatment is used for the large containers. A combined detergent-antiseptic proved very useful for rinsing glasses in public-houses.

HEALTH EDUCATION

Dr. **Robert Sutherland** discussed how health tion could help in improving food hygiene. The task a complex one, for besides the specific intestinal in there is the risk of tuberculosis and other diseases drinking raw milk, and there is the large problem infantile enteritis from which 1 in 200 babies die reaching one year of age. Pending the time pasteurisation can be universally applied, he mended that raw milk should be boiled before given to children, while the toll of deaths from and vomiting could be reduced by a concerted effort increase the proportion of women who breast-fed babies—at present only 1 in 2 do so for the first ti four months of the baby's life. Education of the c mercial food-handler is the joint responsibility of Ministry of Health, the food industry itself, and local authority. The Ministry is preparing a film food and drink infections, and in conjunction with Public Health Laboratory Service is always ready help local authorities in the investigation of outbreaks food-poisoning. Large catering firms could lead the way towards improved food and kitchen hygiene. Difficulties about equipment and staff should not be exaggerat since ignorance and apathy are often the main brunt of the health education will fall on the authority, and here the C.C.H.E. is anxious to in arranging local educational programmes. These d be aimed first at the leaders in food-hygiene ition—key personnel in the food trade, sanitary ctors, doctors and nurses, school teachers, and h organisers; then the rank and file of food-lers, kitchen staff, waitresses, and the like; and ly, the housewife and general public. A course of lecture-demonstrations devised in conjunction the Central Public Health Laboratory has been urated in the London area, and arrangements are made for similar courses to be given throughout ountry. These courses should be supplemented by publicity, posters, and leaflets from practitioners atients with intestinal infections, and from the cal officer of health to food-handlers and housewives. lar inspection of catering establishments should be d out by officers whose approach will be that of ducator rather than the policeman.

* * *

ny practical points were made in the general ssion—e.g., the lack of sanitary facilities on farms; enalisation of food-handlers for sickness absenteeism; suggestion that public-houses should lose their es if they do not conform to certain requirements; oor standards of meat inspection; and carelessness e distribution of food. That many of the diffi-s could be overcome was shown by an outline of rogramme of food hygiene which has been put into n in the Guildford area.

summing-up, Lord WOOLTON felt that the most tant message that emerged from the conference "No dirty fingers in the people's food!"

STREPTOMYCIN ARRANGEMENTS

PPLIES of streptomycin are still strictly limited, and tunately there is not enough to treat every case of culous meningitis or miliary tuberculosis. This s that doctors or hospitals trying to get patients tted to one of the beds now set aside for strepto-n treatment will sometimes be unsuccessful. It would ps be unwise to set up a waiting-list for these beds, the chances of recovery are greatest in early cases. plications by doctors for the admission of patients reptomycin treatment should be made to the nearest e following hospital or other centres.

rculous Meningitis and Miliary Tuberculosis

don area.—Emergency Bed Service (Monarch 8515); ; London Hospital; Middlesex Hospital; St. Bartho 's; St. Mary's; St. Thomas's; or Hospital for Sick ren, Great Ormond Street.

vinces.—Birmingham Children's Hospital, Ladywood ; Bristol General Hospital; Cardiff Isolation Hospital; General Hospital; St. James' Hospital, Leeds; Alder (Children's) Hospital, Liverpool; Royal Southern Hos- Fazakerley, Liverpool; Manchester Royal Infirmary; l Victoria Infirmary, Newcastle; or Children's Hospital, ern Bank, Sheffield.

land.—Four regional committees have been set up, the chairmanship of the deans of the university faculties dicine, to select patients for treatment at City Hospital, leen; Bangour Hospital, West Lothian; Royal Hos- for Sick Children, Glasgow; or Knightswood Hospital, ow. Applications from doctors should be made through edical officers of health.

rthern Ireland.—Inquiries should be addressed to the h departments.

enzal Meningitis

ndon area.—London Hospital; Middlesex Hospital; artholomew's; or St. Mary's.

ovinces.—Queen Elizabeth Hospital, Birmingham; rtment of Medicine, Cambridge University; Welsh onal School of Medicine, Cardiff; School of Medicine, s; Alder Hey (Children's) Hospital, Liverpool; Man-er Royal Infirmary; or Radcliffe Infirmary, Oxford.

quiries with regard to streptomycin treatment for tuberculous cases, other than influenzal meningitis, be made to Prof. Clifford Wilson, Medical Unit, lon Hospital.

In England Now

A Running Commentary by Peripatetic Correspondents

A PRETTY subject for a thesis, treatise, brochure, or Penguin which has not—so far as I know—hitherto received adequate treatment would be the Rise and Fall of Swooning. True, attention has often been drawn to the oddness of the fact that something which was *apparently* as common seventy years ago as constipation is today as dead as duelling, dodos, or Dundrearys. But much more than this is wanted; such a treatise should have at the very least sections on the statistical, physiological, psychological, social, and literary aspects of "the swound." Of these, far the most important would be the critical statistical approach, including an examination of class incidence—I suspect that only chlorotics and social climbers among the working-classes indulged in the practice—and above all keeping a wary eye on the possibility of a grossly exaggerated incidence in novels owing to the extreme convenience of the swoon as a literary device.

Perusal of some of the works of the lesser female mid-Victorian novelists—besides affecting my style—suggests that the following scene must have often occurred. The novelist easily and rapidly achieves some sort of everyday situation such as is always cropping up—e.g., the humble girl whom the Baronet married in a fit of spleen has (*a*) staged a faked suicide, (*b*) subsequently produced a baby in an Italian convent, (*c*) developed smallpox at Twickenham [sic] and been rendered unrecognisable by all, (*d*) had her boy rescued from drowning in the Thames by its father, who had of course immediately got himself remarried to a cold, heartless, highborn Beauty. Enter dripping Baronet to humble peasant cottage bearing son to restore him to unknown humble peasant mother—or so *he* thinks.[*] I can imagine the Bertie Wooster of the period looking over the novelist's shoulder and saying: "What ho! Aunt Agatha, bit of a tricky situation you've got into, what? I mean to say, you've got to extravasate, if that's the word I mean, the Baronet and the beazel. Perhaps Jeeves could bring that bulge behind his ears to bear on the subject." And Jeeves, resourceful as ever, would cough deprecatingly and say: "If I might venture to intrude a suggestion, Madam, the situation calls for a swoon." All is then well, and, if the authoress is feeling particularly daring, the Heroine's dress might be sufficiently disarranged to reveal the strawberry mark on her wrist and thus disclose to the Baronet her true identity.

Anyway, I am sure there is a catch in this swooning business somewhere, and I appeal to Professor Greenwood to let us have the Facts.

* * *

One of my colleagues has developed a unique technique in the conduct of his viva-voce examination. "What are the signs and symptoms of an intracranial tumour?" he asks. "Headache, vomiting, and optic neuritis, aren't they?" he continues before the candidate has time to answer. "What are the chief causes of hæmoptysis? Pulmonary tuberculosis, mitral stenosis, bronchiectasis, eh? Any others besides carcinoma of the lung? Only very rare ones don't you think?" "What's the incubation period of measles? Less than a week? No?"

By this time, the candidate, having satisfied himself that he is not fast asleep and dreaming, and—although this is more difficult—having persuaded himself that the examiner is not to be suspected on the *timeo Danaos* principle, wisely keeps his mouth shut for the remainder of the interview with the exception of an occasional yes or no to supplement his nods of acquiescence.

I have not seen him at work during the clinical examination, though I can well imagine that he carries on in much the same fashion—"Examine this man's heart. Where's the apex-beat? Here in the fifth space, isn't it? Put your stethoscope there. Are there any murmurs? A systolic and a diastolic? Yes?"

But I visualise the danger; a candidate either hypnotised to a state of mental paralysis, or, if he still

factory and a large amount of raw infected milk is still being consumed. Large-scale handling and preparation of food needs expert supervision but it is in the retail distribution that most trouble arises. While improvements in kitchen and personal hygiene are urgently needed, Sir William Savage recounted some of the difficulties: shortage of crockery and cutlery, and of washing facilities particularly during rush hours; staffing problems; inadequate cold storage; and wash-basins inconveniently placed if present at all. He did not favour regular medical examination of food-handlers but suggested that all cases of illness in catering establishments should be reported to the medical officer of health. He thought we should determine which are the essential matters in food hygiene and make our legislation more precise and practical so that there could be a better control over hygiene in the kitchen. To this end, he suggested, a national committee of experts and administrators might be appointed.

A great deal of work has been done on the physics and chemistry of food to ensure a better micro-biological control—e.g., on heat penetration and lethal heat points, moisture and salt content, and hydrogen-ion concentration.

CONTROL OF INFECTIONS

In the afternoon session, Dr. **Robert Cruickshank**, director of the Central Public Health Laboratory, Colindale, discussed four measures in the control of food-borne infections—education of the food-handler; public-health supervision of catering establishments; protection of food against bacterial contamin sanitation of food utensils and food-containe described the progress being made alone th the U.S.A. Education is better than comp courses of three lecture-demonstrations by a specially trained sanitary inspector, medical health, and bacteriologist have been organised American cities with the help of the U.S. Publi Service, which supplies films, lantern slides, pos as described in their pamphlet *Guide to Safe Food* A beginning has been made with similar co sanitary inspectors, school-canteen supervisors, and personnel among food-handlers in this country. tunately the rank and file of the food-handlers are poorly paid and of low-grade intelligence, so edu is difficult, but the introduction of a minimum wa a greater realisation of their importance to the health may attract a better grade of worker. Pro is made under the Food and Drugs Act, 1938, for vision of food-handling establishments, but the e legislation has not gone far enough, and, what is sanitary inspectors do not have time to pay visits which might stimulate the management and to higher standards of food hygiene. Consid should be given to the training and appointment of officers, male or female, whose duty it would supervise catering establishments and organise tional courses in food hygiene.

As regards medical supervision, existing regul prevent a typhoid carrier from being a food-hand a water-works employee, while sufferers from int infections or sore throat can be debarred from ha milk. But a much wider provision of medical c required for all food-handlers so that any infective i can be immediately reported and properly investi bacteriologically as well as clinically. The effect of and suitable temperature in allowing bacterial m plication in prepared foods indicates the urgent nee much more cold storage, particularly in restaurants canteens where for one reason or another food has to be prepared and cooked hours before it is eaten. food manufacturer should also aim at minimising manual handling of food by the greater use of machi Flies can be eliminated by screens and D.D.T. and ve kept at bay by a kitchen cat.

Improperly cleansed crockery and cutlery may some part in the spread of intestinal and respir infections, and much progress has been made detergents and a reliable dish-washing drill in preven such a risk. Washing either by hand or machine is ca out at temperatures of 120–140°F, with detergent pow or sulphonated alcohol to ensure proper cleansing of utensils; this is followed by rinsing for half a minute 170–180°F, which sterilises the utensils and obviates need for wiping crockery; clean dish-cloths must be for cutlery. Similar treatment is used for the large fo containers. A combined detergent-antiseptic mixture proved very useful for rinsing glasses in public-houses.

HEALTH EDUCATION

Dr. **Robert Sutherland** discussed how health ed tion could help in improving food hygiene. The tas a complex one, for besides the specific intestinal infec there is the risk of tuberculosis and other diseases drinking raw milk, and there is the large problem infantile enteritis from which 1 in 200 babies die reaching one year of age. Pending the time pasteurisation can be universally applied, he mended that raw milk should be boiled before given to children, while the toll of deaths from diarr and vomiting could be reduced by a concerted effort increase the proportion of women who breast-fed t babies—at present only 1 in 2 do so for the first three four months of the baby's life. Education of the c mercial food-handler is the joint responsibility of Ministry of Health, the food industry itself, and local authority. The Ministry is preparing a film food and drink infections, and in conjunction with Public Health Laboratory Service is always ready help local authorities in the investigation of outbreaks food-poisoning. Large catering firms could lead the way towards improved food and kitchen hygiene. Difficul about equipment and staff should not be exaggera since ignorance and apathy are often the main obst.

brunt of the health education will fall on the authority. and here the C.C.H.E. is anxious to in arranging local educational programmes. These be aimed first at the leaders in food-hygiene tion—key personnel in the food trade. sanitary tors, doctors and nurses. school teachers. and organisers; then the rank and file of food-ers. kitchen staff, waitresses. and the like: and y. the housewife and general public. A course of lecture-demonstrations devised in conjunction the Central Public Health Laboratory has been urated in the London area. and arrangements are made for similar courses to be given throughout ountry. These courses should be supplemented by publicity, posters. and leaflets from practitioners atients with intestinal infections. and from the cal officer of health to food-handlers and housewives. lar inspection of catering establishments should be d out by officers whose approach will be that of ducator rather than the policeman.

* * *

ny practical points were made in the general ssion—e.g., the lack of sanitary facilities on farms; nalisation of food-handlers for sickness absenteeism; suggestion that public-houses should lose their es if they do not conform to certain requirements; oor standards of meat inspection: and carelessness e distribution of food. That many of the diffi- es could be overcome was shown by an outline of programme of food hygiene which has been put into in the Guildford area.

summing-up, Lord WOOLTON felt that the most tant message that emerged from the conference "No dirty fingers in the people's food!"

STREPTOMYCIN ARRANGEMENTS

PLIES of streptomycin are still strictly limited, and tunately there is not enough to treat every case of culous meningitis or miliary tuberculosis. This s that doctors or hospitals trying to get patients tted to one of the beds now set aside for strepto- in treatment will sometimes be unsuccessful. It would aps be unwise to set up a waiting-list for these beds, the chances of recovery are greatest in early cases. plications by doctors for the admission of patients reptomycin treatment should be made to the nearest e following hospital or other centres.

rculous Meningitis and Miliary Tuberculosis

don area.—Emergency Bed Service (Monarch 8515); s; London Hospital; Middlesex Hospital; St. Bartho-'s; St. Mary's; St. Thomas's; or Hospital for Sick ren, Great Ormond Street.

vinces.—Birmingham Children's Hospital, Ladywood l; Bristol General Hospital; Cardiff Isolation Hospital: s General Hospital; St. James' Hospital. Leeds; Alder (Children's) Hospital, Liverpool; Royal Southern Hos-, Fazakerley, Liverpool; Manchester Royal Infirmary; l Victoria Infirmary, Newcastle; or Children's Hospital, ern Bank, Sheffield.

land.—Four regional committees have been set up, the chairmanship of the deans of the university faculties dicine, to select patients for treatment at City Hospital. deen; Bangour Hospital, West Lothian; Royal Hos- for Sick Children, Glasgow; or Knightswood Hospital. ow. Applications from doctors should be made through medical officers of health.

thern Ireland.—Inquiries should be addressed to the h departments.

enzal Meningitis

don area.—London Hospital; Middlesex Hospital; Bartholomew's; or St. Mary's.

vinces.—Queen Elizabeth Hospital, Birmingham; rtment of Medicine, Cambridge University; Welsh onal School of Medicine, Cardiff; School of Medicine, ls; Alder Hey (Children's) Hospital. Liverpool; Man- ter Royal Infirmary; or Radcliffe Infirmary. Oxford.

quiries with regard to streptomycin treatment for -tuberculous cases, other than influenzal meningitis, be made to Prof. Clifford Wilson, Medical Unit, don Hospital.

In England Now

A Running Commentary by Peripatetic Correspondents

A PRETTY subject for a thesis, treatise, brochure, or Penguin which has not—so far as I know—hitherto received adequate treatment would be the Rise and Fall of Swooning. True, attention has often been drawn to the oddness of the fact that something which was *apparently* as common seventy years ago as constipation is today as dead as duelling. dodos, or Dundrearys. But much more than this is wanted; such a treatise should have at the very least sections on the statistical, physiological, psychological, social. and literary aspects of "the swound." Of these, far the most important would be the critical statistical approach, including an examination of class incidence—I suspect that only chlorotics and social climbers among the working-classes indulged in the practice—and above all keeping a wary eye on the possibility of a grossly exaggerated incidence in novels owing to the extreme convenience of the swoon as a literary device.

Perusal of some of the works of the lesser female mid-Victorian novelists—besides affecting my style—suggests that the following scene must have often occurred. The novelist easily and rapidly achieves some sort of everyday situation such as is always cropping up—e.g., the humble girl whom the Baronet married in a fit of spleen has (*a*) staged a faked suicide, (*b*) subsequently produced a baby in an Italian convent, (c) developed smallpox at Twickenham [sic] and been rendered unrecognisable by all, (*d*) had her boy rescued from drowning in the Thames by its father, who had of course immediately got himself remarried to a cold, heartless, highborn Beauty. Enter dripping Baronet to humble peasant cottage bearing son to restore him to unknown humble peasant mother—or so *he* thinks.* I can imagine the Bertie Wooster of the period looking over the novelist's shoulder and saying: "What ho! Aunt Agatha, bit of a tricky situation you've got into, what? I mean to say, you've got to extravasate, if that's the word I mean, the Baronet and the beazel. Perhaps Jeeves could bring that bulge behind his ears to bear on the subject." And Jeeves, resourceful as ever, would cough deprecatingly and say: "If I might venture to intrude a suggestion, Madam, the situation calls for a swoon." All is then well, and, if the authoress is feeling particularly daring, the Heroine's dress might be sufficiently disarranged to reveal the strawberry mark on her wrist and thus disclose to the Baronet her true identity.

Anyway, I am sure there is a catch in this swooning business somewhere, and I appeal to Professor Greenwood to let us have the Facts.

* * *

One of my colleagues has developed a unique technique in the conduct of his viva-voce examination. "What are the signs and symptoms of an intracranial tumour?" he asks. "Headache, vomiting, and optic neuritis, aren't they?" he continues before the candidate has time to answer. "What are the chief causes of hæmoptysis? Pulmonary tuberculosis, mitral stenosis, bronchiectasis, eh? Any others besides carcinoma of the lung? Only very rare ones don't you think?" "What's the incubation period of measles? Less than a week? No?"

By this time, the candidate, having satisfied himself that he is not fast asleep and dreaming, and—although this is more difficult—having persuaded himself that the examiner is not to be suspected on the *timeo Danaos* principle, wisely keeps his mouth shut for the remainder of the interview with the exception of an occasional yes or no to supplement his nods of acquiescence.

I have not seen him at work during the clinical examination, though I can well imagine that he carries on in much the same fashion—"Examine this man's heart. Where's the apex-beat? Here in the fifth space, isn't it? Put your stethoscope there. Are there any murmurs? A systolic and a diastolic? Yes?"

But I visualise the danger; a candidate either hypnotised to a state of mental paralysis, or, if he still

factory and a large amount of raw infected milk is still being consumed. Large-scale handling and preparation of food needs expert supervision but it is in the retail distribution that most trouble arises. While improvements in kitchen and personal hygiene are urgently needed, Sir William Savage recounted some of the difficulties: shortage of crockery and cutlery, and of washing facilities particularly during rush hours; staffing problems; inadequate cold storage; and wash-basins inconveniently placed if present at all. He did not favour regular medical examination of food-handlers but suggested that all cases of illness in catering establishments should be reported to the medical officer of health. He thought we should determine which are the essential matters in food hygiene and make our legislation more precise and practical so that there could be a better control over hygiene in the kitchen. To this end, he suggested, a national committee of experts and administrators might be appointed.

---

* See *Can Wrong be Right?* by Mrs. S. C. Hall. Tauschnitz. 1868.

Prof. G. S. Wilson remarked that ptomaine poisoning from decomposition of food is a myth and that the various types of food-borne intestinal infection—acute gastro-enteritis, bacillary dysentery, and enteric fever—are due to contamination of the food, usually undetected by the senses, with specific germs. The increasing tendency to communal feeding means that the contamination of one article of food may involve 200–300 workers or school-children and not just 2–3 members of a household. The source of the infecting germs is, in typhoid and dysentery, the fæces of cases and carriers, and since it is often impossible to say who may be a carrier, and since contamination of the hands with bowel germs is practically unavoidable, hand-washing after use of the w.c. should become a universal social habit. The salmonella food-poisoning group is found in a variety of animals—cattle, pigs, poultry, vermin—and as an example of how infection can be spread he instanced the recent outbreak in Essex traceable to an infected pig in a slaughterhouse with secondary contamination of pressed beef in the butcher's shop. The staphylococcus, which has now been incriminated in many food-poisoning outbreaks involving ice-cream, cheese, trifle, gelatin-glazed sausage meat, &c., is derived from the human nose and skin, so with a high nasal carrier-rate and the frequent occurrence of skin infections and septic sores among food-handlers the opportunities for staphylococcal contamination of food are great. Foods in which rapid bacterial growth is most likely to occur are milk and milk products; synthetic cream, ice-cream, and custards; made-up dishes such as pies, brawn, pressed beef, and cooked sausage; soups, gravies, and stews; and canned foods *after* the tin has been opened. Professor Wilson gave illustrative examples of outbreaks of food-poisoning and discussed some of the principles of prevention.

Mr. L. H. Lampitt, d.sc., chief chemist of the Lyons Laboratories, pointed out that a great deal of self-education in food hygiene has been done by the large catering firms and that no large-scale outbreak of food-poisoning has been attributed to his firm in the past twenty years despite a staff of 20,000 and a service of some half a million meals a day. They have adopted a three-tier system of education: inspectors are specially trained to supervise production and investigate complaints; all reports of inspectors are available to managers of departments, to whom faults of staff are also reported; and simple demonstrations are given to staff about personal hygiene and about the dangers of direct or indirect contact between raw and cooked foods. The main obstacles to a higher standard of food hygiene are human inertia which requires constant correction, the present standards of behaviour which make good discipline difficult, and supply problems in equipment, staff, and materials. A great deal of work has been done on the physics and chemistry of food to ensure a better micro-biological control—e.g., on heat penetration and lethal heat points, moisture and salt content, and hydrogen-ion concentration.

CONTROL OF INFECTIONS

In the afternoon session, Dr. Robert Cruickshank, director of the Central Public Health Laboratory, Colindale, discussed four measures in the control of food-borne infections—education of the food-handler; public-health supervision of catering establishments; protection of food against bacterial contamin sanitation of food utensils and food-containe described the progress being made alone the the U.S.A. Education is better than compu courses of three lecture-demonstrations by a specially trained sanitary inspector, medical health, and bacteriologist have been organised American cities with the help of the U.S. Publi Service, which supplies films, lantern slides, post as described in their pamphlet *Guide to Safe Food* A beginning has been made with similar co sanitary inspectors, school-canteen supervisors, personnel among food-handlers in this country. tunately the rank and file of the food-handlers are poorly paid and of low-grade intelligence, so ed is difficult, but the introduction of a minimum w a greater realisation of their importance to the health may attract a better grade of worker. is made under the Food and Drugs Act, 1938, for vision of food-handling establishments, but the e legislation has not gone far enough, and, what is sanitary inspectors do not have time to pay visits which might stimulate the management and to higher standards of food hygiene. Consid should *be given to the training and appointment of* officers, male or female, whose duty it would supervise catering establishments and organise tional courses in food hygiene.

As regards medical supervision, existing regu prevent a typhoid carrier from being a food-hand a water-works employee, while sufferers from int infections or sore throat can be debarred from h milk. But a much wider provision of medical c required for all food-handlers so that any infective l can be immediately reported and properly investi *bacteriologically as well as clinically.* The effect of and suitable temperature in allowing bacterial plication in prepared foods indicates the urgent ne much more cold storage, particularly in restaurants canteens where for one reason or another food has to be prepared and cooked hours before it is eaten. food manufacturer should also aim at minimising manual handling of food by the greater use of machi Flies can be eliminated by screens and D.D.T. and ve kept at bay by a kitchen cat.

Improperly cleansed crockery and cutlery may some part in the spread of intestinal and respir infections, and much progress has been made w detergents and a reliable dish-washing drill in preve such a risk. Washing either by hand or machine is ca out at temperatures of 120–140°F, with detergent pow or sulphonated alcohol to ensure proper cleansing of utensils; *this is followed by rinsing for half a minute* 170–180°F, which sterilises the utensils and obviates need for wiping crockery; clean dish-cloths must be u for cutlery. Similar treatment is used for the large foo containers. A combined detergent-antiseptic mixture h proved very useful for rinsing glasses in public-houses.

HEALTH EDUCATION

Dr. Robert Sutherland discussed how health ed tion could help in improving food hygiene. The task a complex one, for besides the specific intestinal infect there is the risk of tuberculosis and other diseases drinking raw milk, and there is the large problem infantile enteritis from which 1 in 200 babies die bef reaching one year of age. Pending the time w pasteurisation can be universally applied, he re mended that raw milk should be boiled before given to children, while the toll of deaths from diarr and vomiting could be reduced by a concerted effort increase the proportion of women who breast-fed t babies—at present only 1 in 2 do so for the first three four months of the baby's life. Education of the c mercial food-handler is the joint responsibility of Ministry of Health, the food industry itself, and local authority. The Ministry is preparing a film food and drink infections, and in conjunction with t Public Health Laboratory Service is always ready help local authorities in the investigation of outbreaks food-poisoning. Large catering firms could lead the wa towards improved food and kitchen hygiene. Difficult about equipment and staff should not be exaggera since ignorance and apathy are often the main obstacl ly possess the experience in dealing with voluntary ers desired by Dr. Harding. For the time being activities have competed for the services of these odies, though at no previous time has there been ch opportunity to use them in association with the ct-nursing service.

district nurses are the only section of the nursing unity who are associated with the health services, stinct from the hospital services. Their position ves to be as widely appreciated by all who are rned with the health of the people as their services their patients.

C. E. A. BEDWELL

Chairman, Metropolitan Federation of
don, S.E.24. Queen's District Nursing Associations.

,—Miss Steel (Oct. 4) aptly describes the problem ed by me in my previous letter (Sept. 27) as the an's-land of social medicine, and she seems to agree this territory could well be covered to a considerable t by voluntary workers. Whether the supervision ese workers is effected through the health visitor the local authority, or the almoner at the divisional h centre referred to by Miss Sayle, seems to me terial—a question in fact of availability of nnel.

e chairman of the Nursing Recruitment Committee, ng in the *Times* of Oct. 8, refers to the shortage alth visitors and to the extension of their duties the National Health Service Act comes into force 48. It is clear that very careful use of all our ed medical social workers will be essential in the ahead, if the ever-widening fields of work which be their province are to be properly covered. My is that those voluntary workers who for so many have satisfactorily filled a gap in our social services be given an opportunity to help cover that part e field where specific medicosocial training is not sary.

don, S.W.10. A. E. B. HARDING.

MENINGITIS LEPTOSPIROSA

R,—In stressing the importance of anicteric Weil's se, particularly that form presenting as an innocent meningitis, Dr. Buzzard and Dr. Wylie (Sept. 20) recorded cases almost identical with others seen in pshire during the past ten years.

have now had the good fortune to see some 40 cases roved Weil's disease; about half remained anicteric ughout, and over a dozen of these have presented ses of meningitis showing pleocytosis in the cerebro-al fluid (C.S.F.). These too were in young people were apparently infected by contact with river er, though 3 had done nothing more daring than lle. One, an A.T.S. girl of 30, had had no such sure, but her billet was shown to be rat-infested.

ll my cases, however, have shown several features, ical and laboratory, which seem to have been lacking he Oxford series; and it was these very features ch directed attention to the correct diagnosis. All wed muscle tenderness of varying degree which sted until convalescence had been established. I e come to rely so much on this sign that in searching Weil's disease during this summer it has seemed icient when going through the infective-hepatitis ds to squeeze each patient's biceps.

hough I have not found nitrogen retention approach-that seen in the icteric cases, yet blood-urea findings e always been suggestively close to the upper limits normality for young people; and my figures have n higher than those recorded by Buzzard and Wylie. ave seen levels of 50 mg. per 100 ml. and higher in st of the cases. This examination was, however, de two and sometimes three days earlier than in Oxford series. It seems possible that nitrogen ention is a very early feature, and as I have written where,[1] I feel that "this is by far the most important gle laboratory finding" in the early stages. In nchester it was arranged that Dr. C. H. Wrigley, the norary pathologist, should estimate the urea content the C.S.F. whenever pleocytosis with normal chlorides s found; this led to a correct diagnosis in several early cases. In no case was there an excess of polymorphs in the C.S.F.; indeed, the cells have been almost entirely lymphocytes, and case 1 from Oxford with 88% polymorphs must be unusual.

During what has surely been the most tempting summer for bathers in a generation I have seen no cases of Weil's disease in Germany, and I have wondered if the same brilliant sunshine which led possible victims into the water also cut short the life of the young leptospira, which is known to dislike direct sunlight. I understand that no cases have been diagnosed in Winchester this summer—an experience unusual in recent years. I recall that the period July 27 to Sept. 13, 1946, during which all the Oxford cases were seen, was characterised by peculiarly British "summer" weather.

KENNETH ROBERTSON.

REVOLT FROM THE BEDPAN

SIR,—Stimulated by your advice and encouragement I designed, with the engineer of this hospital, a chair for use in taking patients to the W.C.; it closely resembles that used for eight years in the Central Hospital, Orebro, which is described by Professor Bohmansson and Dr. Malmros in your issue of Oct. 4.

These chairs have now been used for several months, and I can endorse the views of your contributors on their extreme usefulness. The work of the nurses is reduced and a distasteful task almost eliminated from the ward. Patients greatly prefer to be taken to the W.C. in these chairs and to defæcate in decent seclusion and in a comfortable and effective position; and the effort is much less than that involved in the use of the bedpan. Patients with advanced tuberculosis can use the chair with advantage.

The valuable suggestion of your contributors should be widely adopted in hospitals. Most advances in treatment seem to add more work to overburdened staffs; it is refreshing to meet one which diminishes the amount of work to be done and at the same time greatly improves the comfort and welfare of patients.

County Sanatorium, Clare Hall, South Mimms, Barnet.

F. A. H. SIMMONDS
Medical Director.

SIR,—Having read with interest the article by Professor Bohmansson and Dr. Malmros, I should like to submit what I believe to be an advance on their suggestion. I have devised a bed which is located over a water-closet pan, and can be manipulated by the patient. The bed has a flap which can be raised to make an opening for the water-closet, and the whole bed can be lowered or raised to allow the patient to sit in a normal position during defæcation. The bed can be operated without the presence or assistance of nurses, and it can be used without moving the patient from bed, thus covering the needs of the bulk of the chronic sick in public-assistance institutions. The cost of fitting the water-closet pans would soon be recovered by the saving of labour, and the offensive odour from bedpans would be eliminated.

Drawings for this bed are in the hands of a firm of hospital-bed manufacturers (Messrs. Whitfields), and it is hoped that a prototype will shortly be in operation.

Boston, Lincs. W. G. BOOTH.

CONVALESCENT HOMES

SIR,—As a patient recently returned from a convalescent home, perhaps my experience may guide those trying to bring about improvements. I was taken to the home from a London hospital, and since it was the first time, after a severe major operation, that I had been dressed and out of the hospital ward, I arrived almost in a state of collapse. The front door was opened by a domestic servant who, without greeting, reprimanded me for being late. I had expected to go straight to bed, but the front door having been shut on my son who had brought me, I was asked to follow her upstairs. I looked at the formidable flight with dismay but managed to crawl unaided to the landing, where I had to stand and wait while the maid unpacked my case. Having been shown my bed in a dormitory for ten, I was asked to come downstairs and see the matron. On

preserves his equanimity, fearful of expressing any disagreement, accepting even the most preposterous nonsense. I would like to see one, invited, let us say, to hear loud bronchial breathing, protesting irritably and vehemently, "No I don't, I'll be d—d if I do." He ought certainly to pass, whatever his performance in general; he would be the right stuff for a good doctor.

* * *

Bus-drivers in New York have an incredible job, for there are no conductors. The two doors at the entrance and exit are opened by the driver pressing a button. The passenger gets on at the driver's end and drops a nickel or a dime into a machine rather like a coffee-grinder. If he intends to transfer to another bus, or return before 4 P.M., he gets a ticket from the driver —otherwise no tickets are needed, for there is only one fare whatever the distance. When all have paid their fares, the driver closes the doors, puts his foot down hard, and off you go. Fluid flywheels make for smooth starting. As the bus proceeds the driver turns a handle and starts the coffee-grinder, which churns up and counts the money. The driver picks the coins out at the bottom of the churn and stacks them in a rack, so he can give change to those foolish enough to need it. He then probably has to count extra coins, odd transfer tickets, &c., and make an entry in his log. At the next stop he calls the name of the street, opens the doors, watches the new passengers deposit their coins, issues tickets, closes the doors, watches the traffic and the traffic lights, and starts off again. It really is an amazing act. It seems remarkable that so much should be put on the shoulders of one man, but they tell me he is well paid for it. I missed the humour and courtesy of the London bus conductor, but one cannot blame the New York driver if he keeps strictly to the job on hand.

* * *

Mr. Raffazzia was my first patient on my first firm, and we took each other very seriously. Ever since then he has haunted the hospital. Indeed, he says St. Malaprop's is his second home. It scarcely seems possible to walk through Outpatients without seeing him brooding in some queue. One careless glance and I am trapped: with gentle sweaty fingers he holds my sleeve and talks . . .

Teetering nervously on one foot I gasp: "I really can't stay—I'm late—I've got a lecture—I must go—they're waiting for me in the ward—I'm due in the theatre." All useless cries. He fixes me with the mild milky stare of cataract, and asks eagerly: "Do you remember that day when Nurse Broadbeam dropped the tray?"

For weeks now he has been pestering me to see his daughter. He's very worried about Lucrezia. She's in love with Enrico, and yet won't marry him—says she'd rather have a weekend at Brighton. "It seems so immoral," laments Mr. Raffazzia, "and I'm sure it would do her good to talk it over with a Lady Doctor." "But I'm not qualified." "Never mind," he goes on remorselessly, "you ought to be."

So the other day I had coffee with Lucrezia. She explained that she didn't mind a bit of fun. But marriage? No! She wasn't going to lose her privacy not for anyone. "But what do you do in your privacy?" I asked unhappily. "Surely you could get used to having a husband around, especially as you love Enrico—why must you always be alone in your room?" For the first time she looked embarrassed. After a moment's hesitation she leant across the table and whispered: "I eat biscuits in bed."

* * *

He had been telling me about the model jet-plane. Now he looked at the rusty automatic machine and went into his state of abstraction. At last he came out of it. "Grandpa," said he, "when you were young could you *really* get chocolate out of a thing like that?" "Yes," I replied. "And matches?" "Yes." "For a penny?" "Yes." "Without being registered or having a book?" "Yes." "I *should* have liked it then." "But you wouldn't have had a model jet-plane." "I wouldn't have wanted it," he said; and I felt more hopeful.

Letters to the Editor

A CHRISTMAS APPEAL

SIR,—Christmas comes but once a year, and comes should bring good cheer. I therefore to your readers to help those who have to look to for whatever extra comforts may come their way.

The beneficiaries of the Royal Medical Fund are either aged or infirm practitioners, or wives, widows, or children, and but for the grace any one of us, or our families, might be in like . I hope subscribers to the fund will send an donation to make this Christmas a little less grim. I earnestly ask those who are not subscr show their sympathy for their less fortunate col not only by sending Christmas gifts, but by b regular supporters of the fund.

Contributions and subscriptions should be sent secretary of the Royal Medical Benevolent Fund, 1 House, Manor Fields, Putney, London, S.W.15, marked "Christmas Gifts."

ALFRED WEBB-JOHNSON
President, Royal Medical Benevolent F

INCIDENCE OF POLIOMYELITIS

SIR,—In your note of Sept. 20 (p. 448) you sugge implication that the true incidence of poliomy at the present time is probably much below, and no more than half, the weekly notification figures. recent experience in Leeds supports this view.

The monthly notifications have steadily risen 1 in April to 3 in May, 6 in June, 15 in July, 19 in and 25 in September, suggesting a continued incidence. A closer analysis of the figures however, that whereas in April, May, and June notifications were true cases, in July, August, September out of 59 notifications there were only accepted cases, the remaining 26 requiring revisio diagnosis. During the last week of September t were 11 notifications, but only 3 of these are now rega as definite cases.

The increasing awareness of poliomyelitis has resulted in a greater number of abortive cases diagnosed. For instance, whereas in June all 6 cases showed definite paralysis, in September only of the 15 accepted cases had paralysis, the 9 being of the abortive type.

The diagnosis of poliomyelitis in the early stages often difficult if not impossible, and doctors have responded to the appeal to isolate and notify suspicion; this has inevitably meant revision of in a substantial proportion of cases. If such as have been obtained in Leeds are common any assessment of the progress of the epidemic on notification figures must be highly fallacious. It however, seem to be a fair assumption that the ep is declining quicker than the notification figures imply.

J. F. WARIN
Leeds. Deputy Medical Officer of Health.

*** Our correspondent presents useful evidence t the cases notified have included a rising number which the provisional diagnosis of poliomyelitis erroneous. It should not be deduced from this, howe that the epidemic has attacked fewer people than number notified. Probably the large majority of of poliomyelitis are not clinically recognisable as and therefore escape notification altogether.—ED. L.

SOCIAL MEDICINE

SIR,—It is remarkable that Dr. Beryl Har (Sept. 27) does not appear to know the fine work of district nurses, and Miss Steel (Oct. 4) refers to the in which they labour so happily as a "no-man's-land. The district nurse is par excellence the family doctor' coadjutor. The Ministry of Health have approved health-visitor course for district nurses under auspices of the Queen's Institute, who are thus alr equipping themselves for further demands likely to under the National Health Service Act. For years district nurses have had the collaboration of memb of the Order of St. John and Red Cross Society, so they r possess the experience in dealing with voluntary s desired by Dr. Harding. For the time being ictivities have competed for the services of these dies, though at no previous time has there been h opportunity to use them in association with the t-nursing service.

district nurses are the only section of the nursing mity who are associated with the health services, inct from the hospital services. Their position s to be as widely appreciated by all who are ied with the health of the people as their services their patients.

C. E. A. BEDWELL
Chairman, Metropolitan Federation of
Queen's District Nursing Associations.

MENINGITIS LEPTOSPIROSA

—In stressing the importance of anicteric Weil's e, particularly that form presenting as an *innocent* eningitis, Dr. Buzzard and Dr. Wylie (Sept. 20) ecorded cases almost identical with others seen in shire during the past ten years.

ve now had the good fortune to see some 40 cases ved Weil's disease; about half remained anicteric ghout, and over a dozen of these have presented es of meningitis showing pleocytosis in the cerebro- fluid (C.S.F.). These too were in young people were apparently infected by contact with river though 3 had done nothing more daring than e. One, an A.T.S. girl of 30, had had no such ire, but her billet was shown to be rat-infested.

my cases, however, have shown several features, l and laboratory, which seem to have been lacking e Oxford series; and it was these very features directed attention to the correct diagnosis. All d muscle tenderness of varying degree which ted until convalescence had been established. I come to rely so much on this sign that in searching eil's disease during this summer it has seemed ent when going through the infective-hepatitis s to squeeze each patient's biceps.

ough I have not found nitrogen retention approach- at seen in the icteric cases, yet blood-urea findings always been suggestively close to the upper limits rmality for young people; and my figures have higher than those recorded by Buzzard and Wylie. e seen levels of 50 mg. per 100 ml. and higher in of the cases. This examination was, however, two and sometimes three days earlier than in Oxford series. It seems possible that nitrogen tion is a very early feature, and as I have written here,[1] I feel that "this is by far the most important e laboratory finding" in the early stages. In chester it was arranged that Dr. C. H. Wrigley, the rary pathologist, should estimate the urea content e C.S.F. whenever pleocytosis with normal chlorides found; this led to a correct diagnosis in several early cases. In no case was there an excess of polymorphs in the C.S.F.; indeed, the cells have been almost entirely lymphocytes, and case 1 from Oxford with 88% polymorphs must be unusual.

During what has surely been the most tempting summer for bathers in a generation I have seen no cases of Weil's disease in Germany, and I have wondered if the same brilliant sunshine which led possible victims into the water also cut short the life of the young leptospira, which is known to dislike direct sunlight. I understand that no cases have been diagnosed in Winchester this summer—an experience unusual in recent years. I recall that the period July 27 to Sept. 13, 1946, during which all the Oxford cases were seen, was characterised by peculiarly British "summer" weather.

KENNETH ROBERTSON.

REVOLT FROM THE BEDPAN

SIR,—Stimulated by your advice and encouragement I designed, with the engineer of this hospital, a chair for use in taking patients to the W.C.; it closely resembles that used for eight years in the Central Hospital, Orebro, which is described by Professor Bohmansson and Dr. Malmros in your issue of Oct. 4.
